The shared approach to design and implementation of HIA is based primarily on that of EIA as a whole, and within this framework a standardized methodology is being developed (Asian Academy for Heritage Management online). An HIA is carried out when it is red flagged during the development process as a result of “screening,” a review of all project proposals to identify those which may have potential impacts on heritage. The nature and scale of the HIA baseline study, including definition of the study area, requirements for the desk-based study, field surveys and any additional data collection and the staffing and expertise needed for the HIA team are identified as part of “scoping” and writing of the terms of reference.

The methodology used in HIA is based on a comprehensive understanding of the current or baseline situation; the type, distribution, and significance of heritage resources as revealed through desk-based study and additional data acquisition, such as archaeological investigations, built heritage surveys, local interviews, and recording of crafts, skills, and intangible heritage. This is systematically integrated by the use of matrices with information on the nature and extent of the proposed engineering and other works to identify potential sources of impacts on heritage. Mapping of location and distribution of heritage in relation to proposed works or changes is a critical component of this baseline along with the assessment of the condition of resources.

The “significance” of heritage resources is a fundamental part of the process and should be assessed and factored into the overall assessment of impacts being weighed carefully against predicted impacts and the proposed public benefit that will result from loss or compromise to the heritage. This is where training, experience, and professional qualification come into play.

Assessment is then made of each specific impact during the proposed works, for the lifetime of the development and during decommissioning, and an overall assessment of the degree of resulting change. It is very noticeable that guidance documents regularly gloss over the section on implementation of the assessment of impacts. There may be a few hints, examples

of simple matrices or an abstract flow chart but nothing to reliably guide the practitioner through the very complex and demanding tasks of identifying the potential sources of impacts, their nature and extent, how they will combine to act on existing conditions and how they will affect the significance of parts of heritage and the whole.

Several cultural heritage impact assessment (CHIA) methodologies base their assessment on project types such as pipeline, roadworks, mining, port development, or sewerage and provide sectoral guidelines. These describe the types of works associated with the project type and generalized impacts that will result. These can be useful to some extent, but a detailed understanding of engineering works is fundamental, as the distinction between different piling methods, backhoe blades and dredging methods is critical to assessing their impacts.

Detailed proposals are put forward to mitigate the identified negative impacts where necessary with the aim of either maintaining the current status or improving it. Essential tools are designed to monitor the success of the proposed mitigation. Mitigation is essentially a set of proposals to try and maintain the condition of heritage resources at the level described in the baseline study or to improve them. Mitigation proposals must include a monitoring plan with indicators to illustrate the degree of change from existing conditions to during and postproject conditions to evaluate how affectively this is achieved and to ensure that the required mitigation measures really are implemented as laid out in the HIA.

The strength of this process comes from the integration of spatial and distributional data, predictive methods, rigorous matrix methodology, and the consideration of multiple scenarios and solutions based on an understanding of the significance of heritage resources in relation to issues of “public good.”

Who does what and why it matters

Because HIA is integrated into larger strategic plans and development projects, there are players at a number of different levels. There are those who decide whether or not a proposed project needs a HIA, those who write the scope and

tender documents, specialists who actually implement the HIA, reviewers who assess the HIA and approve the project, and finally, those who implement and then monitor mitigation measures.

It is widely acknowledged that professional input into this complex process is essential, but approaches differ on the degree of such input and at what stage it should be required. Some apply strict vetting and listing of professional qualifications while others work on the underlying assumption that a HIA will not be carried out by heritage professionals at all. It is accepted that in the majority of cases it be carried out by someone who is appointed to be the heritage generalist. They will come from some other background, and will most likely be covering heritage on a part-time basis while still being responsible for their own discipline. Heritage practitioners are consulted but not integrated into heritage identification and safeguarding except in “exceptional cases” (Campbell 2009). As a result, there is a risk that poorly informed decisions at the early stages of the HIA will negate later findings and compromise the effectiveness of the whole process.

At stake are issues of transparency and integrity. Professional input is required at every stage of the HIA process, including the early stages of screening to avoid over-reliance on existing heritage lists and inventories and scoping when knowledge of local heritage, project cycle and engineering works is critical. Baseline studies, including additional surveys and studies, as well as the assessment and mitigation design should be carried out by qualified and experienced HIA professionals.

Sequencing of HIA steps

Review of guidelines and HIA reports themselves reveals confusion about which steps of the process need to be carried out before or after others. This is particularly a problem with archaeological sites where archaeological reconnaissance survey and preliminary site evaluation may be recommended at the scoping stage. Again “a limited reconnaissance survey and site evaluation before planning the baseline data collection phase” may well be required, with the possibility of even further investigations at a later stage. Archaeological field

evaluation is a pivotal part of the baseline study and further work may form part of the mitigation plan. Following this kind of schedule, therefore, a potential site could be “investigated” three or four times during an HIA.

Shared vocabulary

It is critical that HIA practitioners use an agreed upon and shared vocabulary to describe basic terms and concepts, particularly when discussing kinds and nature of “impacts” and the “acceptability” of impacts on cultural resources. Terms should be clearly defined at the beginning of every HIA report, based on terms agreed upon by the discipline and used consistently. An assessment based on vague and inconsistent terminology has no internal integrity and can neither achieve its purpose nor help build the wider body of HIA research.

HIA and the community

The role played by community consultation varies widely in HIA approaches. In some cases only passing reference is made to the need to seek stakeholder input, usually in identifying resources in an area. At the other extreme, some approaches state that no mitigation should be considered unless it has total stakeholder support, and that the best mitigation is that proposed by stakeholders (Rogers 2011). Clearly, the ideal lies somewhere between, once again highlighting the role of HIA as a tool for negotiation and settlement.

When to do an HIA

In most western countries the assessment of potential impacts on culture and heritage is a requirement of the existing EIA system, based on consultant input adhering to strict guidelines and reporting requirements. However, there are many parts of the world where EIA does not include consideration of heritage at all and HIA occurs in different contexts. These may include HIA as a donor agency requirement following relevant safeguard policies, at the request of the

UNESCO World Heritage Centre to address issues arising at UNESCO World Heritage properties or as a result of NGO or private sector initiatives in response to proposed urban or rural redevelopment proposals.

The latter has resulted in the development of new and diverse applications of HIA to deal with “real world heritage problems” such as HIA of adaptive reuse proposals for historic properties; to evaluate the sustainability of tourism at heritage places; and impacts on intangible heritage resources and traditional “ways of life” and “spirit of place.” Importantly, HIA has been adopted reflectively to assess the impacts of proposed or ongoing heritage conservation projects, which often pose a grave threat to heritage.

HIA now and in the future

This development of varied approaches and methods of HIA for different agendas has enriched the practice but has also resulted in methodological confusion and mixed standards of implementation and reporting. Guidance to help deal with this situation is increasingly available and increasingly sophisticated including international principles, guidance from international donor agencies and banks, guidance for specific types of heritage, from countries where HIA is part of the EIA process, and for specific types of development. The targeted users vary from site managers to consultant practitioners, government heritage authorities, and funding banks. All state the importance of safeguarding heritage, or at least of tangible heritage, and urge the inclusion of heritage into the formal EIA process.

Looking at these adaptations of HIA informs us regarding the current state of practice and reveals a great deal about the potential of the methodology and how it can be further developed. At the national and regional levels worldwide work continues on setting standards and procedures for HIA. ICCROM has been focusing on the development of methodology for HIA in its many applications, working for example in Asia with the Asian Academy for Heritage Management (AAHM online) and the World Heritage Institute for Training and Research in Asia and the Pacific (WHITRAP) on training and manuals for global

use. Similarly, ICOMOS has prepared guidance specifically for the use of HIA at World Heritage properties (ICOMOS 2011) and the World Bank continues to refine their safeguard policies using impact assessment procedures and approaches.

In recent years there has been a growing interest in developing the theoretical underpinning of HIA. HIA can be seen as one of a suite of tools that help support more sustainable decision-making and planning, but there is a wide range of views as to how effective it can be from a theoretical point of view. HIA like EIA was built upon the rationalist model that if we provide better and more information to decision makers then they will inevitably make better and more rational decisions. This is clearly contrary to political and social reality. Current research and critique of HIA is focusing on these issues and on how to expand, reinforce, and develop the scope of HIA (Roders and van Oers 2012).

The strengths of HIA

HIA is a powerful methodology because it employs systematic examination of the full range of potential events and outcomes, combining overview with detail. It integrates heritage values and authenticity with development visions, engineering works, and stakeholder input to engage with the bigger picture. Most importantly, its findings and recommendations cannot be easily dismissed as just opinion, bias, or selective discussion.

Every HIA generates an expanding database of known and newly discovered heritage resources and galvanizes public interest in heritage under threat (Rogers 2011). At the same time the HIA process can add to asset value, not just for developers, but also by identifying and evaluating previously unknown or unacknowledged heritage items and increasing the value of heritage sites. An HIA is not just for protecting sites, but can also be used as a vehicle to provide benefits that enhance and improve them.

Authorized Heritage Discourse

NATSUKO AKAGAWA

The University of Queensland, Australia

The term “authorized heritage discourse” (AHD) was introduced into the field of heritage studies by Laurajane Smith in her now widely cited monograph *Uses of Heritage* (Smith 2006). Its introductory chapter, “The Discourse of Heritage,” sets out a cogent argument that heritage discourse and practice have been and continue to be shaped by a particular “discursive practice” that determines the way heritage is thought about and practiced.

In the 1970s and 1980s the discipline of archaeology had become subject to a wave of critical self-reflection. It came to be recognized that “the work done by archaeologists is not neutral, self-contained or objective”: archaeology involved a process of writing about the past in the present, and inevitably the “interpretation of the past is affected by present ideology” (Shanks and Tilley 1987). Since the 1980s this understanding of the discursive nature of archaeology has encouraged further interrogation of the nature of what Shanks and Tilley identified as the ideological construction of this “linguistic medium.”

More recently, archaeology’s claim to stewardship has been questioned in relation to debates concerning heritage. Archaeology, Waterton and Smith argue, is one of the “forms of knowledge [that have] become privileged in maintaining authorized historical and cultural narratives” and in this capacity has gained “a certain degree of power to influence particular cultural and social debates and meanings” (Waterton and Smith 2009, 17). The effect of such discourses is to “maintain the legitimacy of elite history and the social hierarchies that flow from this” and to deny the claims of “subaltern groups” that offer a different sense of historical and social experience (Waterton and Smith 2009, 17). More broadly, these dominant western assumptions and conclusions have come to be embedded, through

UNESCO conventions, in the management of heritage internationally, from the Venice Charter of 1964 to the World Heritage Convention, which was adopted by UNESCO at the General Conference in 1972.

Since the publication of *Uses of Heritage* in 2006, reference to AHD has become pervasive in debates about heritage and in the analysis of heritage practice and management at both global and national levels. It is therefore useful to begin with Smith’s starting point, which was that certain objects, practices, and ideas of the past only become “heritage” when they are so defined. This view of heritage involves two further related assumptions: that the definition of heritage is at all times dependent upon an “authorized discourse,” typically as articulated by an “authorized body” that gives specific heritage meaning to particular places, objects, and practices; and that this discourse has historically been dominated by assumptions derived from “western” heritage traditions. This interpretation of heritage practice therefore problematizes “heritage” as a field of political power, typically monopolized at the nation level by national governments in conjunction with owners of “elite cultures” and “experts” and internationally by and through global institutions.

The identification of AHD also contains a demand for the recognition of global cultural diversity in heritage discourse and practice. Second, it directs critical attention to the power conferred upon heritage “experts” to determine what heritage is and thus to deny the right of “the subaltern” to offer alternative interpretations. Third, if AHD is construed as a critique of any formal “authorized” attempt to define and predetermine heritage practice and, implicitly, as an advocacy for recognizing the possibility of an infinite degree of diversity in what constitutes heritage, its targets along both these lines can extend infinitely.

The critique exerted by AHD reflects a broader shift in western intellectual practice as well as in global geopolitical relations that took place in the latter decades of the twentieth century. There is in the first place an obvious debt to the

work of Michel Foucault, to critical discourse analysis, and, more broadly, to the insight of postcolonial theory, which has influenced the direction of western research in the social sciences and humanities since the 1970s. Already in the 1980s, what was then referred to as “the dominant ideology thesis” had emerged as a critique within heritage discourse (Abercrombie, cited in Tunbridge and Ashworth 1996, 47). Employing Bourdieu’s concept of “cultural capital,” which posits that, typically, “governments or ruling elites will project a message legitimating their position,” the dominant ideology thesis held that heritage interpretation was of obvious interest for “government or ruling elite appropriation,” given its the significance in the definition of national identity (Tunbridge and Ashworth 1996, 48).

At the same time, dissatisfaction with the dominance of the Anglo-western interpretation of heritage and heritage practice at a global level reflected developments in international relations (Akagawa 2014). The early UNESCO conventions designed to define, promote, and safeguard heritage of outstanding universal value, were seen to reflect an exclusively western European intellectual tradition (Akagawa 2014). This western idea of heritage was seen to originate in the writings of John Ruskin (1819–1900) and in the activities of William Morris (1834–96) and of the Arts and Crafts Exhibition Society, which the two of them founded in London in 1887, although longer lineages can be suggested (see also Akagawa 2014). This, however, did not prevent nonwestern states from adopting the principles of the World Heritage Convention into their own national heritage frameworks. For newly constituted postcolonial nations in Asia and Africa, UNESCO’s recognition constituted an important element in international and internal recognition and enhanced the significance of emblems of national identity, reinforcing various processes of national consolidation. Nevertheless, the convention’s criteria for determining what could gain international recognition as “heritage” gradually came to be recognized as discriminatory of nonwestern assumptions and practices, while, within nations, emerging democratic processes also liberated a desire for the recognition of regional and local-community identity and for agency in making heritage decisions.

In the course of the 1990s, debates within UNESCO were gradually pointing to a more inclusive approach to heritage, influenced by awareness of alternative approaches. This tendency was manifested in a number of important enactments, such as the Recommendation on the Safeguarding of Traditional Culture and Folklore (1989), the Living Human Treasures protocol (1993), and the Proclamation of Masterpieces of the Oral and Intangible Heritage of Humanity (1998). The claim for recognition of greater diversity in official heritage discourse enacted by UNESCO was finally recognized in 2001 through the adoption of the Universal Declaration on Cultural Diversity. In 2003 this declaration paved the way for UNESCO’s Convention for the Safeguarding of Intangible Cultural Heritage (ICH), officially adopted in 2005. As Akagawa (2014) notes, however, even then, advocates of an enlarged conception of heritage, notably led by Japan and by UNESCO’s Japanese director at the time, Koichiro Matsuura, initially found little support.

The 2003 ICH Convention significantly broadened the concept and the parameters governing the practice of heritage in the context of UNESCO. It determined that practices, representations, expressions, knowledge, skills—as well as the instruments, objects, artifacts, and cultural spaces—needed to be recognized as “heritage” by this global institution—and, by extension, by its states parties. Most importantly, as later detailed in its operational directives, it emphasized the central role of “community” as integral to the entire process of heritage identification and nomination by the state party.

It could thus be argued that a central criticism of AHD has been largely addressed within the peak international heritage body, whose guidelines influence much national practice. Indeed, Askew (2010) has argued that the AHD case, applied to the current state of heritage discourse, is exaggerated, claiming that “Smith’s uncompromising conclusion about the alleged persistence of the Authorized (Eurocentric) Heritage Discourse ... is belied by the dominance of non-Western practices listed as intangible heritage as well as the transformation of the World Heritage List itself and the influence of non-Westerners in key positions of the bureaucracy” (Askew 2010,

32). In any case, Askew argues, advocates of the AHD critique “misread the character and extent of UNESCO’s power, since it is with the nation-states that the capacity for innovation and oppression ultimately lies” (2010, 32).

While this argument (which effectively repeats the case earlier put by Tunbridge and Ashworth against the proposition of a dominant ideology thesis) may have legitimacy at the international level, Smith’s conception of AHD is much broader. It relates equally to the role of national governments in determining heritage practice at the national level and explicitly applies to all the bodies and experts involved in articulating authorized discourse. In the burgeoning literature on the implementation of the 2003 ICH Convention, this concern is clearly manifested. Although the concept of “intangible heritage” has made it possible for nonofficial heritage claimants to make a case for being recognized, recent literature nevertheless points to continuing obstacles in gaining official recognition that local-community groups face (Smith and Akagawa 2009; Akagawa and Smith 2018). Furthermore, as Askew (2010) also points out, the very framework established by UNESCO requires in the first place that non-formal groups must first gain the imprimatur of national governments, which are the only bodies entitled to submit nominations to UNESCO and its various “expert” committees.

Thus, through its own mechanisms and through the related activities of its states parties, UNESCO not only continues to accord authority over the “regulation and the legitimization of group identity but ultimately imposes interpretation on what ‘community’ is” (Waterton and Smith 2010, 12). Smith (2015) has concluded that all the signs indicate that the 2003 Convention is still overly dependent on AHD and that the addition of intangible heritage has done little to challenge the dominance of western assumptions concerning the universal values that underlie heritage. Rather, it has merely been “treated as another concept to be tacked on to existing definitions ... as something ‘special’ to certain non-western groups, rather than as something more universally applicable” (Smith 2015, 138). What is still required, she argues, is “a framework that privileges the community/sub-national orientation of intangible heritage” and, in the

first place, a recognition that “all heritage is intangible” (Smith 2015, 141).

Community Heritage

MARGARET PURSER

Sonoma State University, USA

Community heritage (CH) research explores a specific community's relationship to its past, and usually to some notion of place. CH projects are designed to be both collaborative and inclusive; they thus document often diverse narratives about a community's history, the nature of its collective identity, or its remembered experience relative to some larger historical event. Community heritage projects are rarely interpretively neutral; they aim to tell untold stories, create civic unity, increase visibility, or raise awareness. They are frequently undertaken in regulatory contexts in which policy frameworks and economic development agendas form a powerful backdrop for how and why the project is undertaken, and what will be done with the results. Community heritage projects can be conducted by scholars from academic institutions, or by practitioners representing a range of government agencies and civic organizations. Many are very grassroots in their inception and structure. Interest in community heritage extends well beyond archaeology as a discipline, and so engages archaeologists in a rapidly growing and wide-ranging professional discussion that attempts to define community heritage as both a concept and a research practice. Other disciplines and professions involved include public historians, geographers, folklorists, or historic preservationists working for museums, heritage organizations, government agencies, and descent communities. Finally, community heritage projects are increasingly found all over the globe, and the resulting professional discussion is commensurately diverse and richly comparative. The examples cited below are intended to give a sense of this geographical range.

This entry describes "community heritage" projects, research trajectories, and theoretical discussions that explore the ways in which a specific community defines its connection to both

past and place. It does not cover "community archaeology," which is a distinct practice described in a separate entry (see HERITAGE AND COMMUNITY ARCHAEOLOGY), although many community heritage projects include an archaeological element. Nor does this entry address work done with local communities who are affected by their proximity to officially or externally designated "heritage sites," in the contexts of tourism, site stewardship, physical displacement, degree of cultural affinity, or other impacts. These three separate kinds of endeavor do however share a recent intellectual history, growing from the intertwined developments over the past three decades of national and international heritage industries, and postmodern critiques of a series of related disciplines from anthropology and archaeology to history, geography, folklore, and sociology. Practitioners involved in all three areas often move from project type to project type, and increasingly read and publish across these disciplinary and methodological lines.

The growing interest in community heritage among archaeologists represents a return to the idea that local knowledge has validity, after twentieth-century repudiation of local knowledge in preference for more objectified and objectifying definitions of a "scientific" archaeological practice. At least three trends have led this return: increasing demands for inclusion and authority by indigenous groups in several colonialist and postcolonial contexts, the rise and intellectual maturation of historical archaeology globally, and the increasingly sophisticated cross-disciplinary literature on the nature of "heritage" itself. The shift is also part of a larger renewed interest in all aspects of the local: an exploration of local scales of human social organization and lived experience as opposed to larger ones. In particular, community heritage research feeds into a growing body of research that sharply problematizes the relationships between localized and localizing social forces, and broader national or global sets of institutional structures, identities, and power relations.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0101

Community archaeology projects frequently provided the critical intermediate step to draw archaeologists into community heritage (Little and Shackel 2014). They offered both an intellectual framework and a methodological platform. Created for a wide range of reasons, conducted in a variety of ways, and occurring all over the world, these projects have made archaeologists key participants in the development of the community heritage discourse. But community archaeology can also be seen as the context in which many archaeologists first came to grapple with the concept of community heritage, both as a subject for study, and as a broader field of practice in which their own work took place. For a detailed discussion of these challenges to community archaeology in grappling with the nature of community in a series of examples from South Africa and Zimbabwe, see Chirikure and Pwiti (2008).

The most profound impact of this has been on the archaeologists themselves. It has challenged their notions of what both “community” and “heritage” mean, and has created cracks in their understanding of what they do, and what their work means, and to whom. These cracks can be explored as a series of fundamental questions for archaeologists to ask themselves.

What is “community”?

By far the most trenchant critiques of community heritage research coming from practitioners themselves have been aimed at uses of the term “community” (Waterton and Smith 2010). Oversimplified assumptions about the internal homogeneity and shared identity of any given community are seen to stem from romanticized, nostalgic, and ultimately elitist notions of the concept. This fails to take into account the presence of internal diversity, the contested nature of community identity, and the power relations that shape social interaction within the community itself, and between it and the larger social and political context in which it exists. Such critiques are not new, and draw heavily from a larger social sciences literature.

These powerful critiques have led community heritage research towards more nuanced understandings of the ways in which communities, however defined, interact with, articulate, build and transform notions of heritage. Assumptions of homogeneity have given way to analyses of internal diversity, and the contests between and among community constituencies. Public discussions about defining heritage and the meaning of the past are explicit components of more recent projects. Communities are increasingly understood as inherently dynamic, and their ongoing processes of change include redefining what counts as heritage, and how individuals are connected to that heritage. Many examples of the tensions between communities and the professional heritage practice in a variety of European contexts can be found in the compendium *Between Imagined Communities and Communities of Practice* (Adell et al., 2015).

What counts as “heritage”?

In this context, the second fundamental question has been about the nature of heritage. In many ways, this discussion has been driven by increasingly problematic encounters between archaeologists and others conducting community heritage research, and heritage management policies and regulatory guidelines, particularly those with a list-based approach, such as the UNESCO World Heritage List, or the National Register of Historic Places in the United States. Communities often identify as significant many places, sites, and structures that do not match the formal criteria defined in such classificatory systems. David Morgan and colleagues recount particularly trenchant examples of this gap revealed by surveys of perceived losses caused by the devastation of Hurricane Katrina in 2005 (Morgan, Morgan, and Barrett, 2006). Furthermore, communities and practitioners alike characterize as “heritage” many more aspects of shared identity than archaeological sites, architecture, or monuments. And as with the definitions of “community,” “heritage” is now commonly understood to be contested, dynamic, and always under construction. Perhaps even more importantly for the study

of community heritage itself, heritage is understood to be something actively used by people to define and construct sustainable notions of “community.” Three ideas underpin this expansion of what counts as heritage—intangible heritage, place and landscape, and the nature of participation.

The label “intangible cultural heritage,” although the phrase is not used universally, and has its own complicated developmental history, can mean the simple inclusion of non-material practice that local people consider integral to their collective identity: performative arts, local narratives, local calendars of events, and locally held and communicated bodies of knowledge about myriad aspects of daily life: livelihoods and occupations, medicinal practices, religious rituals, children’s play, foodways, and so on. The labeling of such practices as “heritage” inevitably emphasizes heritage as something that is alive, and which must be performed to be maintained, rather than being only an inventory of unaltered buildings, sites, or structures to be preserved in perpetuity. This performative and commemorative approach to culture and identity positions community heritage projects and research as relevant in the present and to the future. Performances of what is inherited from the past tie people to places, pass on specialized knowledge to newcomers and children, distinguish insiders from outsiders, and provide the canvas on which different community members paint their agreement, opposition, exception, and conflict. Communities also use these performances to edit the connections between past and present: to choose what is remembered, how, and what is forgotten, as (for example) research with Inuvialuit and Maori communities have shown (Lyons and Marshall 2014).

Identifying such practices as a category of heritage can lead to them being catalogued, inventoried and officially listed, and this can introduce new debates over authenticity or claims of cultural primacy. It can constrain the very dynamism and situated nature of the practice that makes it work as this kind of living heritage. Li’s study of this interactive process between heritage practitioners and local communities in Chinese villages documents exactly this tension, as well as the creation of entirely new “communities of knowledge production” in the process (Li 2014).

Community-based heritage research also dissolves any hard and fast dichotomy between “tangible” and “intangible” heritage and exposes the links between the two. Notions of heritage that document and define this interconnection are supported by approaches that use place and landscape as dynamic social practices. These efforts borrow from a well-established archaeological interest in cultural landscapes as a more inclusive analytical frame of reference for individual sites and features, as well as being a subject of scholarly study in its own right. They have been reinforced by relatively recent heritage policy adaptations of the landscape framework for management purposes. Community heritage projects regularly explore the relationships and synergies between a given community and its collectively defined physical setting.

How do we do these kinds of projects, and what counts as results?

The ideas behind community heritage research also challenge the notion that a deepening of local or even regional “community” involvement in “heritage” can be accomplished merely by increased public outreach (for instance, by increasing site visitation at officially recognized heritage sites). Such assumptions betray an “assimilationist” mindset that assumes the primacy of officially recognized heritage for everyone (Waterton and Smith 2009, 12) and fails to recognize the significance of other sites, alternative narratives, and more diverse identities.

For that reason, as well as because of the conceptual reframing mentioned above, the development of new or revised methods and procedures have been an integral part of the development of community heritage research. Some of the broader reconceptualization is specific to the archaeological or heritage disciplines, but much is inherent in collaborative or participatory community research done by any discipline. The adaptation to these methodological, analytical and interpretive changes has focused on three core challenges: (1) integrating the new types of data and modes of analysis (particularly those documenting less tangible heritage or drawn

from visual, textual, or oral sources) with conventional archaeological science; (2) modifying older methodologies or developing new ones, so as to accommodate or support multivocality, inclusivity and collaboration; and (3) articulating research between established, “official” heritage management frameworks and alternative (and multiple) concepts of heritage authenticity, significance, and integrity as defined by community members. Meeting these challenges has for many archaeologists redefined research goals and outcomes, such as the expected results of community heritage research, and has raised the question of in what way it is “research.” Such questions go well beyond the notion of “applied science,” and feed into larger discussions of decolonizing archaeology and other Western social sciences.

Community heritage projects require shared authority as well as multivocality. Their goal is not necessarily a single narrative nor to “test” oral traditions and local knowledge against archaeological analysis or heritage presumptions. In CH projects, the community is not a source of data but a set of collaborative research partners. Research methods have to be designed to elicit not just facts, but also values, opinions, judgments, or statements of significance, and they must work with both consensus and diversity. Sarah De Nardi’s work in Italy is a powerful example of this kind of work (De Nardi 2014). There are difficulties in dealing with such diversity. CH research risks creating fixed categories or authoritative narratives from what had been fluid, dynamic, and localized interactions. Furthermore, what should the heritage practitioner do when confronted with stories that a community does not want to tell, because they are perceived as unflattering, or dangerous?

Considerable effort needs to be placed in CH projects on embedding full community participation—community consultation, input, and collaborative decision-making—throughout the entire project, from initial research design to final outcomes. These efforts have required methodological borrowing from the social sciences, notably of rigorous assessment tools. But finding better ways to define and measure participation, to record and document project data transparently and accessibly, and assessing project impacts, outcomes, or effectiveness, are

new methodological needs only beginning to be addressed.

Newer technologies have also played a part in this methodological development. Participatory GIS, social media and web-based digital media provide new platforms for achieving widespread participation and dissemination. They have proved particularly useful for articulating a community’s understanding of its heritage with official heritage policies or protocols, for instance through their creation of alternative maps and narratives. Perhaps even more powerfully, these same methods have been used to create “virtual” restorations of sites, buildings, neighborhoods, or entire communities that no longer exist as physical places, as in the website that made visible Rosewood, an African American town in Florida destroyed in a 1923 race riot (González-Tennant 2015). Social media also become an ever-more diverse platform for contestation and alternative interpretation, circumventing the heritage expert’s narrative control and creating a much more fragmented realm of exchanges, enabling for example what Morgan and Pallascio describe as “remediation” (Morgan and Pallascio 2015, 261).

These methodologies have engendered their own critiques and challenges, however. Principal among these is their highly technological nature. While access has widened (but is by no means global), authorship is often still restricted to experts, or at least mediated through them. Their flexibility and open-endedness can create significant public expectations of access and currency that must be met by those maintaining the databases and websites. Making these aspects of community heritage projects sustainable over the long term has become a significant challenge, particularly for locally supported and grassroots projects.

The discussion about how to do community heritage projects extends to the question of what counts as “results.” The present author’s 12-year-long community mapping project in Levuka, Fiji (Purser 2012) ultimately succeeded in having the community’s version of the town’s character accepted as part of the site’s nomination to UNESCO’s World Heritage List, but ultimately it was the process of creating the map, rather than the map itself, that was considered most valuable by the community members who

participated. Archaeologists are accustomed to a more finite project with a concrete result, generally in a “site report.” But community heritage projects often have goals well beyond the production of a documented narrative of local heritage: for example, to raise visibility, to help an underrepresented group have its voice heard, to strengthen social unity and connection to place, or to develop a sense of shared heritage. In this context, some argue that community heritage projects should be seen as process-driven, rather than product-driven, and that the doing of the project is itself a main outcome (e.g., Little and Shackel 2014). This approach puts even greater emphasis on questions of authorship, sponsorship, and above all, sustainability for such projects over time. It raises again the questions of how CH projects serve any larger intellectual inquiry into the nature of community heritage as a subject for study, and how insights gained from that study can feed back into the design of future projects.

Conservation Plans

KATE CLARK

University of Suffolk, UK

A conservation management plan sets out the value and significance of a heritage site and how that will be retained in any future management, including in terms of use, alteration, or development (see CULTURAL RESOURCES MANAGEMENT and PLURALITY AND MULTIVOCALITY). Such plans are based on a thinking process that puts the way people value heritage together with technical conservation methods. The process of conservation management planning is central to values-based heritage management (HERITAGE AND VALUE-BASED APPROACH).

A plan may be prepared in order to help manage change (for example, in support of an application for new work or development), to underpin routine cultural resource management, in support of fund-raising or grant applications, or as part of an application to inscribe a site in a register. In relation to archaeology, plans are often prepared to inform the management of archaeological sites, and the discipline of archaeology can play a significant role in the planning process.

Although the majority of plans have been prepared for historic buildings, sites, landscapes, or larger heritage items such as ships, the values-based conservation planning process is equally applicable to any kind of heritage, from an individual object in a museum to a large urban conurbation (see URBAN ENVIRONMENTS). Conservation management plans are closely related to other kinds of heritage plans, such as World Heritage Site Management Plans, conservation master plans, heritage management plans, and parks management plans.

Contents of a values-based conservation plan

Although a plan is usually presented as a written document, the critical factor is not its format or length, but the heritage thinking process that underpins it. The steps in the planning process are presented next.

Understanding

The better a site is understood, the easier it is to articulate its value and to manage change in an informed way. The elements that make up the understanding of a site can include its history and how it has changed through time; and these elements draw on oral, documentary, and archaeological evidence, its component elements (e.g., landscape elements, collections, buildings), and its current management and designations. As that information can be extensive, appendices, gazetteers, or databases are often used. Archaeological information is critical to this part of the plan and may cover buildings or landscape archaeology, or the application of analytical techniques such as stratigraphy, phasing, and typologies in order to understand how a site has changed through time. This section can also include information about communities linked to the place and about intangible heritage, memory and remembrance (see MEMORY AND REMEMBRANCE), and traditions—all based on oral history and community consultation.

Assessment of value and significance

The core of the conservation plan explains why the heritage is of value and to whom. It is based on the understanding set out above, and then informs the later policies.

Conservation plans normally explore two kinds of values:

- **Designation values.** These represent the reasons why a site may have been designated or protected. Heritage designations are usually based on a specific range of values—typically architectural, archaeological, historical, or scientific—and there may be a requirement for a particular level of significance (e.g., Outstanding Universal Value in the context of World Heritage sites, or national importance for scheduled ancient monuments in the United Kingdom). This can also include natural heritage designation values, and values that relate to any other form of protection (eg registers of historic ships).
- **Wider public and community values.** Most heritage sites are also important in ways that go beyond the reasons for which they are designated. Those values may include amenity values, spiritual values, social or community values, leisure and use values. There may be aspects of the site that are not protected but are important. Those wider values could include the benefits of conserving the site, for example, social and economic benefits. Some form of community engagement or consultation is essential to understanding these values.

Nonwestern values can be included in the planning process (see *HERITAGE: NONWESTERN UNDERSTANDINGS*) whether they are part of the reasons for the designation or part of the wider issues to be taken into account in managing it.

As well as identifying the different ways in which people value the site, many plans also capture the degree of significance of those values. A protected or designated site will usually have special significance at a state, national, or international level. However, some practitioners also provide greater clarity on the relative importance of different parts of the site in order to assist with future decision-making.

Management issues/vulnerability

This part of the plan should explore management issues such as ownership and control, neighbors and local community concerns, deterioration (see *DETERIORATION*), funding, conservation issues,

maintenance and repair, the wider setting and context, commercial activities, interpretation, visitor facilities and management, the different uses of the site, security, staffing or volunteers, presentation, and health and safety. All of those activities have the potential to impact on the value and significance of the site in a positive or negative way.

Policies for retaining value and significance

The policies in the plan should connect value and significance with future conservation, alteration, use, and management. They might cover anything from interpretation to future use, conservation treatments, visitor management, development, maintenance, alteration, security, setting—all informed by an understanding of the significance of the site. There may be generic policies such as encouraging the use of heritage impact assessment in decision-making, as well as specific maintenance or conservation programs.

Implementation and review

Aside from helping with decision-making, the information in a plan can be used in many ways. The research and analysis might inform interpretation strategies or shape the design of new facilities, while the management information can be a starting point for briefing staff, contractors, or partners. The process of involving stakeholders may have benefits in its own right, while a plan also provides a historical record of how and why decisions were made.

As knowledge of a site grows or the management context changes, a plan may become outdated and it may be helpful to review it.

Plans can be used in conjunction with heritage impact assessments (HIAs), which explore the impact of a specific development or plan of work on the significance of a site and looks into how any negative impacts can be mitigated or avoided. Where a plan already exists, a HIA can draw on much of the information in the plan.

Stakeholder engagement

Understanding how different stakeholder groups value a site and feel that it should be managed

is central to the planning process. While a site may be protected for some values—such as its scientific or archaeological value—different community groups may see the site in different ways. Understanding their perspective, including its nonwestern values, is the first step in identifying potential areas of conflict and in working toward shared goals.

Origins and development

Values-based plans have evolved out of traditional site management planning.

General management plans have long been a part of best practice in parks management services in the United States, Canada, and Australia (National Park Service 2006). Generally, such documents set management objectives and then define how they will be achieved; but, for archaeologists and other site managers who work with diverse communities, such as Aboriginal, First Nation and Native American groups, there has been a growing realization of the importance of plurality and multivocality (see *PLURALITY AND MULTIVOCALITY*) in cultural resource management.

Many of the heritage charters that guide heritage decision-making in a European context, for example, the 1931 Athens Charter for the Restoration of Historic Monuments or the Valetta Charter for the Protection and Management of the Archaeological Heritage, make brief references to significance in decision-making, but it was the Burra Charter (Australia ICOMOS 2013) which has done most to reframe this thinking.

Drafted by a group in Australia with experience of both indigenous and European heritage and adopted in 1979, the Burra Charter sets out a process that puts an assessment of significance and value at the heart of conservation management planning and shows how decisions about managing a site should flow from that understanding, as well as from technical conservation knowledge. One of the authors of the original charter developed detailed guidance on conservation planning (Kerr 2013), and such plans have since become a core part of Australian heritage practice. Although originally focused on

European heritage, the values-based process can be applied to any kind of heritage.

In the United Kingdom the Heritage Lottery Fund (HLF) asks for plans to support applications for funding, in order to ensure that applicants understand both conservation and community issues and that their proposals are likely to be sustainable. Plans have now been prepared for a wide range of different kinds of heritage sites, from ships such as the *SS Great Britain* to sites and monuments, churches and cathedrals.

At a global level, World Heritage site management plans are prepared as part of the process of applying for inscription. Such plans explicitly require an understanding of the outstanding universal value of a site as part of the process of management; but they can also refer to the wider ways in which the place matters to people.

The Getty Conservation Institute studied management in four World Heritage sites in order to understand how such plans were developed and used in practice. It showed that, although the site may have been included on the list for its outstanding universal value, in practice site managers needed to respond to a much wider range of ways in which people valued the place, which were often shaped by current issues (de la Torre et al. 2005).

As well as conservation plans, there are now numerous other tools used in values-based planning, including heritage impact assessments, conservation area appraisals, and statements. In association with the Native American Graves Protection and Repatriation Act 1990, plans of action require practitioners to understand the cultural issues associated with the treatment of archaeological remains, while place-making and community engagement strategies such as the England and Wales National Trust's 'Spirit of Place' statements also explore the different ways in which places are valued by people.

Conservation plans remain controversial. Along with an academic literature that is critical of heritage practice, practitioners themselves debate whether conservation is a social or a technical discipline. For some, the preparation of written plans takes resources away from maintaining and managing heritage sites; for others, the time spent in planning is an essential part of the community engagement needed for sustaining sites. Either

way, values-based conservation plans are a practical way of bringing together social and technical approaches to conservation.

Countermapping

DENIS BYRNE

Western Sydney University, Australia

Countermapping refers to practices of mapping that are designed to represent indigenous or local cultural landscapes from the inside, which is to say to represent them against the dominant external cartographic practices which are perceived to efface or misrepresent these landscapes. In an archaeological context, countermapping is employed to spatially articulate archaeological remains which have gone unrecognized by governments and corporations to the detriment of local people or to provide local counter-interpretations of officially recognized archaeological sites and arrays of sites.

The term “countermapping” was first used by the environmental anthropologist Nancy Peluso (1995) to describe the way nongovernmental organizations (NGOs) working with forest-dwelling groups in Kalimantan, Indonesia, adopted cartographic techniques, ordinarily the domain of forestry companies and state resource bureaus, in order to record the location of key food resources, ritual sites, story and song locations, and other key loci in the forests inhabited by these people. The resulting maps were designed to give local people a voice at the tables where vital questions regarding the fate of the forests were being decided. Other anthropologists working in Southeast Asia helped develop the approach (e.g., Brosius, Tsing, and Zerner 2005; Roseman 2003) and it subsequently joined a plethora of other alternative mapping approaches under labels that include indigenous cartography, participatory geographic information systems (GIS), and autonomous cartography. In the time since Peluso’s early work, digital technologies, including GIS and global positioning systems (GPS), have become widely available and have to a great extent democratized map making. While it is important to acknowledge the existence of traditional mapping practices, in which maps

were and are sometimes inscribed in the dirt, on rock faces, on paper, and other surfaces, digital technologies have been important in allowing these customary forms of mapping to evolve to meet present-day needs. Such needs include the archiving of traditional knowledge and ensuring its availability for intergenerational transmission. These exercises in mapping have been carried out by archaeologists collaborating with indigenous groups (for example, Byrne and Nugent 2004) or indigenous groups autonomously mapping the archaeological terrain in their homelands.

Archaeologists operating in the Global South were mostly slow to appreciate and acknowledge that archaeological remains, even those that were millennia old, were frequently an embedded element of the social landscape of contemporary indigenous dwellers in the same terrain. Where they are manifest at the surface, archaeological remains can be considered continuous with a whole universe of marks that we learn to read and navigate in the course of our daily lives and in the context of our cultural world view (Bradley 2002). The participation of archaeologists in countermapping projects has been underwritten by the increasing subtlety of the profession’s ability to engage with the experiential materiality of past life worlds, as seen in the phenomenological archaeology of Christopher Tilley (2010), and in Tim Ingold’s “dwelling perspective” (Ingold 2000). Archaeological traces, while deriving from past behavior and events, are continually recycled back into the contemporary social environment and they can be said to be “regrown” in the lived environment of each new generation. It is in order to demonstrate the truth of this to wider audiences that so many indigenous groups have embraced countermapping practices.

The path-breaking ethnocartographic practices of Peluso (1995), Roseman (2003), and others working with tropical forest dwellers in Southeast Asia demonstrated that forest areas which previously had been depicted on official maps as culturally barren were, in reality, intricately inscribed cultural landscapes, where former swiddens were regarded as storied historical sites, where individual trees were often

known by their own names, and where ridges and gullies were mapped with the territories of spirits and gods. An example of this kind of sensibility being brought to archaeological counter-mapping was Rodney Harrison's collaborative work with the Muruwari Aboriginal people of northwestern New South Wales, Australia (2004; 2011). Focusing on the continued significance to the Muruwari of a now-abandoned campsite they had occupied from the 1870s to the 1940s, Harrison showed how during their periodic visits to the site, the Muruwari sometimes had visions of spirits in human form. Artifacts found there became "extensions of long-dead relatives: powerful, troubling and at times problematic" (Harrison 2004, 205). When visiting such sites, Muruwari people sometimes picked up flaked stone artifacts and rubbed them on their bodies. One Muruwari woman explained, "when you're rubbing the stones over your skin you can get the feeling of ... you sort of get the feeling of the spirits coming into your skin somehow or another" (Harrison 2004, 199). The propensity of these artifacts to not merely evoke the dead relatives who had used and sometimes made the objects but to *presence* them is something a purely archaeological recording of the campsite and its surface assemblage could not hope to reveal. Only by being actively engaged in such mapping or by conducting it themselves can such indigenous people convey the real meaning these places and landscapes have for them.

Thomas and Ross (2013), discussing the integration of archaeological and indigenous knowledge datasets at an Aboriginal stone arrangement site in southeast Queensland, Australia, refer to the way sites such as this are "continually being reformed and resurrected" by their cultural custodians. Unhappy with the way previous exercises in archaeological counter-mapping had been constrained to work with two-dimensional maps, which inevitably fix the cultural landscape at a particular moment in time, they used the Web-based tool Prezi, to allow the viewer to move through the landscape in the way it is believed Aboriginal travelers did in past times. Being Web-based, the "maps" they have created can be updated and modified according to the changing conceptions of the Aboriginal traditional custodians and in line

with the acquisition of new archaeological data (Thomas and Ross 2013, 234).

It is worth remembering that the first exercises in counter-mapping, conducted in the 1990s, had a specifically decolonizing objective. Indigenous people and archaeologists who have worked with various forms of counter-mapping have been conscious of the way archaeology, as practiced in settler colonies and in the Global South, has involved a process of translation in which precolonial archaeological remains are not merely rendered compatible with modern cartographic productions but are made over into state-supported modern ontologies. Reflecting on their work with Mayan communities in Belize and the Mayangna community in Nicaragua, the geographers Joel Wainwright and Joe Bryan (2009) have summarized the downside of counter-mapping in terms of uneven participation in mapping (for example, by indigenous women), its potential to cause internal disharmony among group members with different interpretations of landscape, the risks of causing or inflaming border disputes with neighboring indigenous groups, and, because counter-mapping is often carried out to secure legal recognition of rights to land, the negative effect of the indigenous community's relations with land being articulated as *property*. Nevertheless, in the early twenty-first century, a great deal of creative energy has been devoted to creating an alternative, decolonized space in which indigenous perspectives can be represented in a more-or-less unalloyed form. The technology of 3D digital simulation has had a key role here, resulting in a rapidly expanding universe of online productions, which are difficult to do justice to in a text publication such as this but can be sampled online, for example at Wikipedia's page on the "Indian animation industry" (https://en.wikipedia.org/wiki/Indian_animation_industry, accessed November 27, 2017) and at the Monash Country Lines Archive (<http://artsonline.monash.edu.au/countrylines-archive/>, accessed November 27, 2017). As a result of these developments, there has been a blurring of the boundaries between indigenous archaeological site and landscape representations, digital storytelling, and digital animation designed for revitalizing indigenous languages (<https://rising.globalvoices.org/blog/2016/03/20/series-of-animated-stories->

revitalise-indigenous-languages-in-mexico/, accessed November 27, 2017).

In the days before digital mapping, the paper maps in existence were mostly produced and policed by state authorities and were widely held to be authoritative. The aura of completion that they possessed explains the anxiety of local groups not to be “left off the map,” whether through the ignorance or the strategic intent of official cartographers. Digital mapping, particularly where it is Internet-based, open source, and community-based, has exploded the truth claim of the paper map. A new conception of maps as fluid and democratic has gained currency in “mainstream” (i.e., non-indigenous) society. During the 2010s, open source mapping that aggregates spatial data collected by volunteers, the most prominent example being OpenStreetMap, has resulted in a vast expansion in the number of community mappers, most of whom are not from marginalized or indigenous groups. A number of NGOs now promote and facilitate community mapping. For example, the NGO “historypin” (<https://www.historypin.org/en/>, accessed November 27, 2017) operates a website where anyone can upload and maintain collections of historical photographs, videos, and stories, which effectively act as a mapped, digital platform for place-based public history.

Understandably, much of the countermapping activity in archaeology has been concentrated in the area of archaeological heritage recording and conservation. This relates to the fact that government heritage agencies were collecting spatialized data on local peoples’ heritage sites long before techniques of countermapping became available. Many countermapping initiatives have thus been motivated by a concern to correct what were seen to be distorted or partial inventories and official mappings of local heritage. Two factors are, however, likely to impede the emergence of a universal open-access inventory of archaeological heritage sites. First, the digital maps of these inventories that are maintained by government heritage agencies may be “open access,” but the *entry* of site data onto them is usually restricted by legislation, meaning that only those sites that meet defined criteria and significance thresholds are included. Second, indigenous groups concerned with ensuring that their cultural knowledge is not

publicized, commodified, and commercialized often either maintain their own “closed” spatial databases or decline to have particular categories of sites and knowledge included on government heritage databases.

The overview presented here charts the spread and mutation of countermapping practices since the 1990s. In this process, in-place archaeological traces have been inscribed on a variety of maps intended for a variety of purposes, most of which have been to do with depicting and defining indigenous cultural habitats. The “countermapping” label may be close to the end of its usefulness, but there is every indication that archaeology—both the profession and the stuff—will continue to be caught up in the technology and cultural politics of mapping.

Critical Museology

ANTHONY ALAN SHELTON

University of British Columbia, Canada

Critical museology investigates the practices of applied or operational museology and the range of heritage regimes and policies with which it is always entangled.

Throughout its relatively short history, museology has attempted to present itself as an applied discipline based on a body of empirical knowledge, tested presuppositions, and notions of the common good to sustain its hegemony and utility in supporting museums and related heritage institutions. Its seeming intellectual and logical coherency, ethical conviction, and functional certitude, occlude its political operations, strategies, and changing objectives. The hidden epistemological differences that underlie museology's actual heterodoxy of knowledges and the strategies by which specific forms of national and neoliberal expressions of individualism and personhood have been abstracted and essentialized, stand in fundamental opposition to museology's privileged academic and disciplinary claims. Focused on the theory and practice of museum and heritage management, collections and their curation, exhibition and public engagement, what is usually described as museology is better prefixed as "operational" museology. Although presented as disinterested and universally applicable, *operational museology* is always constructed from specific national histories, governmental practices, and political strategies that usually have their origin in the English or French speaking worlds. The briefest analysis reveals that the extensive personal, institutional, intellectual, and citational networks that underlie most museological discourses and practices, far from having universal application and scientific value, originate in the United Kingdom, the United States, Canada, Australia and New Zealand, and are inadequate as both

models for organizations elsewhere, and as intellectual frameworks to describe the plurality of histories, views, and practices outside their national spheres of operational competency. The universalist presumptions of this anglicized or francophone museology excludes other histories of collecting, institutionalization, and mobilization of collections, and their wider integrations into alternative exhibitionary complexes and coexisting hegemonic projects, it also largely ignores the potential of museology as a vehicle for resistance, critical theories, and counter hegemonic strategies.

Operational museology refers to the underlying imaginaries: bodies of knowledge; rules of application; procedural and ethical protocols; organizational structures; institutional relationships and regulatory interdictions, through which collections are assembled, managed, curated, circulated, reproduced, and expanded. *Critical museology* has developed since the 1970s in opposition to the objectivist claims, universalist pretensions, and ideological effects of operational museology. Critical museology investigates the practices of operational museology and the range of heritage regimes and policies with which it is always entangled. In addition, critical museology scrutinizes the institutions that support cultural and heritage institutions including their professional organizations; accredited academic courses, systems of internship, mentorship and peer review; and their related conference cycles, seminars, and publications through which institutional narratives and discourses are mediated and regulated.

Epistemological positions

Critical museology is based on four fundamental epistemological positions and includes several methodological principles that guide its application. The deployment of these positions and principles sharply distinguish critical from operational museology and enables it to sustain reflexive and critical analysis, destabilize

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0142

essentialist assumptions, and propose ways to transform organizational practices and diversify exhibition genres. It constitutes therefore, both a method of critical analysis and a means for establishing alternative museological and curatorial practices.

Position one: critical museology treats history as a cultural construction through which intellectual and ideational genealogies and disciplinary and institutional legitimations are constructed, mediated, and reproduced. It sees history as composed of culturally constructed event structures that are traced backwards in time to structure causal and deterministic narratives that claim to explain current institutions and material cultures, including museums, galleries, and monuments, and the defining characteristics and operations of heritage regimes. Museums and heritage regimes are situated within specific political, cultural, and event-based structures and cannot be abstracted or reduced to common sets of generalizations or universalist principles.

Position two: critical museology rejects the notion of the collector as a being abstracted from society and culture through the imputation of their individuality and/or universalized psychological disposition. Neither the individual who supposedly embodies these predispositions nor the drive towards possessive and competitive acquisitiveness can be assumed to characterize the whole spectrum of human behavior. The figure of the collector and the instincts that supposedly motivate their activities, far from representing an aspect of common human nature, are the unique creation of certain types of western art historical discourses and psychiatric and psychoanalytical operations, employed by operational museology to legitimate its field of operations. Collectors and their activities exist in specific social and cultural milieus which inscribe their activities within systems of significations and value, and shape behavior, procedures, organizations, optical regimes, and the mechanisms and aesthetic values that govern their utilization and deployment. The relationship between collectors and their assemblages is always specific and cannot be abstracted and essentialized to legitimate collecting institutions.

Position three: objects have no meaning independent of that which is ascribed to them through language and culturally specific classifications.

The meaning and value of materials, objects, or assemblages is always relational and contingent on a wider social and semantic field of relationships that reject mechanistic views of active knowledge acquisition and transference and its reception by supposedly passive subjects. Knowledges and the communities from which they are derived are active, dynamic and in constant change and transformation. It therefore follows that the knowledges they produce and which museums appropriate, synthesize, and seek to disseminate are never naturally bounded, complete, or definitive, but always in a process of expansion and becoming. Similarly, museum visitors do not simply absorb knowledge as presented, but mediate and interpret it according to their own presuppositions and educational, cultural and political backgrounds. Museum knowledges are therefore doubly mediated, first through the methods by which they are synthesized, and secondly through their differential interpretation by visitors and other interlocutors.

From the above three positions, it follows that the empirical or rationalist epistemology on which western museums have been founded, which governs their operation and legitimates their existence, is fundamentally flawed. Empiricism and positivism while insisting on the intelligibility of reality as perceived through the senses and its amenability through plain description, ignore their inability to apply their own epistemology to legitimate their foundational assumptions. Isolated, outside of its own rules of description and criteria for attributing truth and meaning, empiricism ignores the question of the legitimacy of its own criteria of truth, and therefore, not only severs epistemology from method, but occults its own ideological inflections. Empiricism and positivism hypostatize knowledge of "reality" and in so doing favor a naturalized and nonproblematic theory of meaning.

This leads to the *fourth position* of critical museology that holds that museum authority can no longer be legitimated through reference to a universal and transcendental theory of knowledge that locates meaning as independent of human agency. Neither is it permissible to regard scholars and curators as disinterested observers whose special training allow them to "discover" knowledge and the relationship and significance of objects as expressions of universal truth.

These four positions, fundamental to the process of museological deconstruction, constitute a discipline fully compatible with the epistemologies and goals of postprocessual archaeology, new material culture studies, and critical heritage studies. Furthermore, critical museology is dependent on collaborative and indigenous methodologies that through the juxtaposition of alternative epistemologies, methodologies, and the knowledges they generate, contribute to the relativization of the western categories on which operational museology is based. However, critical museology, unlike some of these, in no way advocates the epistemic privileging of one knowledge system over any other in a manner that would assert a different orthodoxy and its attendant power relations. Instead, critical museology aims, from its observation and intervention in operational museology, to sustain an ongoing interrogation that intends to place museums and related institutions in flux independent of stabilized social conventions and values. In this respect operational museology and curatorial practice provide critical museology with a laboratory in which its commitment to heterodoxy is able to impute disciplinary and institutional change and transformation.

Methodological principles

This relativist epistemology leads to a distinctive, though by no means exhaustive set of *methodological principles* that inform critical practice. The first of these, the acknowledgement of the effects and deployment of agency, is foremost to critical museological work. Institutions do not exist independent of complex, cross-cutting networks of often contradictory and conflicting powers and interests, which provide channels for the projection of agency. Museums are connected internationally through formal and informal and real and digital networks and channels. Digital connectivity in particular engenders relationships and networks that sometimes provoke unexpected professional, political, and personal alliances and antagonisms between different interest groups. Through mediating the agencies expressed and directed through these networks, museums—whether administered by

communities, private foundations, or national or municipal governments—always attempt to synthesize a singular politic of patrimony, which links together collections, monuments, and buildings with a specific territory. These heritage regimes are never static, and the values, interpretations, and political economy which they promulgate are usually contested by different interest groups. So great have these differences become in North America and the Middle East that they have become inflated into “culture wars.” Heritage institutions therefore are always subject to the play between internal and external normative and subversive agencies which lend them their complex, shifting and provisional qualities. Critical museology regards the use of categories like “traditional,” “primitive,” “modern,” “Oriental,” and “occidental” that deny agency in favor of transcendental laws and categories, regardless of their intellectual interest, as lacking analytical use and rigor.

The *second principle*: Critical museology views institutions and the knowledge and cultural creations they generate as part of a wider field composed of other institutions and intellectual and creative positions to which they are related. The operations of one institution or set of practices need be understood in relation to others sharing the same field as well as the position occupied by museum analysts who can never stand outside of the field they explicate. Analysts never play solely an observational or recording role, but actively intervene and unintentionally change the field. The foci, the construction of the field of observation, the questions asked, and the perception of the presence of the analyst, must be recognized as part of the field of study.

The *third principle*: In explicating set conditions, phenomena, or experiences analyses also constitute their antonyms, which are unintentionally produced as a residue of that which falls outside the primary category of investigation. The category of “popular art” is part of the residue from defining “elite culture,” or “nature” consists of the residue from defining culture, and not of an untransmutable and objective category that is the same for all cultures and societies. The construction of mutually dependent extensive and exclusionary binary classifications leads to the categorization and configuration of different types of materials and

artifacts and their institutionalization in different types of museums. In effect, by defining the focus of a heritage regime, policy, or institutional specialism, exclusions, which analytically may be as important as the institutionalized categories themselves, are inevitably generated which require acknowledgement and scrutiny.

The *fourth principle*: Critical museology is never exhausted by the deconstruction of operational categories or the explication of social and political strategies. As terms of the dominant discourses or narratives are effectively made transparent, operational museology strives to retain, reform, and perfect its coherency and authority through adopting new practices and terms of engagement, which it partly appropriates from the findings of critical museology and other disciplines and cultural knowledges. In the last few decades, British and Canadian museology has replaced mechanistic with dialectical models of museum communication; exhibition foci has partly changed from a national to a global focus and this in turn has created new organizational structures for circulating collections and knowledge specialists. Moreover, museums have changed from object to public-centered practices. Nevertheless these shifts imply only changes in the conditions and operations of museums which, whether positive or not, are still required to be subject to ongoing critical enquiry. Such adaptations attest to the elasticity of operational museology's hegemonic functionality and its adaptability to changing conditions, which critical museology is charged to expose and transcend.

These four epistemological positions and four methodological principles distinguish critical museology from other forms of critical museological writing. The new museology developing from critical historical research and the art history of the 1980s, best represented by Peter Vergo, while critical of the operational museology that preceded it, did not develop a method or purpose of its own. More recently, collaborative museology has achieved greater success in articulating its political and disciplinary objectives and in distinguishing different methodologies within it. However, its relationship to indigenous methodologies, especially when it tries to generalize these and engage with their abstraction or reduce itself to subservience to one or other

of them, quickly loses intellectual relevance and credibility. In the first it synthesizes and distracts itself by chasing chimeras, while in the second it reduces itself to a series of practices, divorced from disciplinary legitimation, capable of bridging, but not questioning prior established inter- and cross-cultural conditions and relationships. Collaborative museology, by acknowledging the expression of cultural heterodoxy, supports critical museology but because of its political objective and limited view of criticism, usually falls short of it.

For critical museology, the authority commonly attributed to museums is contingent. Instead of them constituting shrines of truth as an older museology once insisted, it regards museums as agencies of interpretation, which hold the promise of a future possible transformation into forums for dialogue and transformation into open rather than closed institutions.

Open and closed museums

The distinction between open and closed institutions is crucial to the understanding of museums. Closed institutions are those that legitimate themselves through transcendental logics on which universalist laws governing classification, causation, determinism and positive or negative evaluations of categories and actions are maintained. They transform abstraction into actions, which they divide and consecrate as either meritorious or contemptible; normative or censured; good or bad, and thereby delineate the boundaries between acceptable and disparaged dogmas and actions. Their embrace of transcendental logic creates communities holding non-contingent, immutable beliefs that impose limits on interpretation and intelligibility, establishes their exclusivity, and regulates their membership. Open institutions, on the other hand, are distinguished by relativist concepts of knowledge based on their contingent, open-ended, agentive and generative propensities and the nonfixity of ethical and moral principles and actions implicit in their transformation. Closed institutions provide universal and comprehensive security, truths, and life principles while narrowing the space of individual freedoms

and intercultural dialogue, and usually adopt authoritarian forms of organization. Open institutions, on the other hand, develop and receive their vitality through critical dialogue, their incredulity towards the metanarratives and arbitrary establishment of borders and boundaries between disciplines, knowledges and cultures, and their exploration of categories like difference, hybridity, and “creolization.”

The distinction between open and closed institutions allows for an alternative classification of museums in which national institutions, still committed to narrating the history, flora, fauna, and intellectual and aesthetic achievements of the resurgent nation-state form one pole of a spectrum whose opposing exemplar is represented by the contemporary art or critical ethnographic museum. Contemporary art has been defined as a form of critical interrogation, exploration, and expression of contemporary existence which possesses its own museology that shares common foci and aspirations with critical museology. The critical ethnographic or anthropological museum, whose potential is more acutely repressed under western capitalism, is represented by world culture museums and a few municipal and university museums including those of Neuchâtel, Geneva, Tenerife, Santa Cruz, and Vancouver, which actively critique and problematize accepted western categories, classifications and interpretations of the world. Different orientations are not determined by types of museums though university and municipal museums usually have more operational latitudes, but by their curators. Outside the western canon, the growing number of indigenous museums and cultural centers in Australia, New Zealand, Canada, Mexico, United States, and Taiwan have established their own museology which directly supports the work of open institutions. Open institutions are an essential component of the movement to transform museums into multiversities. As developed by Paul Wangoola and Claude Alvares, the multiversity combats western universalist knowledge systems by acknowledging that all knowledges are culturally constructed and should be treated as having identical value and heuristic competence within their field of proficiency. Alvares demands a deconstruction of western thought and the history, institutions, and singular concept of science whose continued

dominance, he argues, dismisses other scientific systems and perpetuates a western intellectual dominance that prevents their economic, social, and cultural development. The purpose of progressive thought, for Alvares and Wangoola is to challenge western intellectual hegemony and, through the multiversity, acknowledge the plurality of knowledge systems. The multiversity is then a series of museum displays that attempt to exhibit different cultural themes according to their indigenous rather than their western categorizations, classifications, and significances that represent a concerted, but only too rare example of a decolonizing process. Despite the recent tendency of some museologists to proclaim a new postcolonial museum age, exhibitions other than those on singular native peoples, cultural resources, and organizational structures have everywhere remained resistant to large-scale transformative change.

Cultural Resources Management

KEITH EMERICK

University of York, UK

Closely associated with “conservation” and “archaeology,” “cultural resource management” (CRM) is the suite of legislation, policy, guidance, and professional practices for the management of heritage places. Originally focused on the authenticity of historic fabric, and the preservation of historic places, “heritage” now includes ideas of identity, memory, the intangible, and change. There is now recognition in the West that not everything can be saved and that “change” is both natural and expected. Therefore “heritage management” is now better understood as the ways in which “change” to the historic environment is “managed” to ensure the continuance of “cultural significance.”

Still a relatively young discipline, CRM is the title used in North America, whereas “cultural heritage management” (CHM) is preferred in Europe and Australasia. The effective operation of CRM/CHM relies on archaeology and heritage being part of a defined legal and developmental process. In both the United Kingdom and the United States CRM/CHM is a recognized, largely commercially run professional practice (Doelle and Altschul 2009) usually identified through a step-by-step archaeological procedure to establish the impact of a development on a heritage place and then mitigate its impact. Practice usually includes desk-based assessment, geophysical survey, archaeological evaluation, and modification of the proposed development design or its excavation and publication, known as “preservation by record.” A comparable set of techniques is used for the assessment of the recording of historic buildings in advance of any change to the fabric.

In the United Kingdom “heritage” is a recognized part of the national planning system and developers are required to identify and mitigate

impacts of development on heritage places as a condition of receiving planning permission. In the United States heritage is dealt with at Federal and State levels, but encouragement for individuals and organizations to support heritage preservation is also promoted through the tax system. As a consequence there is an active local and charitable element to preservation in the United States that sustains national and regional heritage places (Stipe and Lee 1988 provides the best overview of the evolution of US preservation practice). However CRM/CHM is not universally applied as many nation states do not include heritage in the development process and do not have a robust heritage infrastructure at national, regional, and local levels. Similarly, for some nation states, such as India for example, heritage is a “living” and omnipresent concept more related to people, tradition, and the intangible rather than something that seeks the preservation of historic fabric.

Origins

Lowenthal argued that the origins of CRM can be traced back to the Classical era (Lowenthal 1985), but also suggests that people have always used the past for the purposes of shaping their particular present, whilst “nostalgia” is a common human trait.

The dramatic social and political changes in nineteenth-century Europe provoked considerable reflection on the past by writers, philosophers, artists, antiquarians, and architects. The movement of large numbers of people from a rural, agricultural to an urban, industrial life created a sense of nostalgia about past lifestyles but fueled concern about increasing physical loss of historic buildings and sites, and this created a desire to identify ways in which change could be managed to either preserve historic places or lessen the damaging impacts on them.

“Restoration” became a key term in ideas about preservation with opposing ideas about the use of new or complementary materials in historic

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0145

sites. The opposing views are best represented by the French architect E. E. Viollet le Duc who proposed using new materials, whilst the English writer, artist and critic John Ruskin considered restoration in all its forms to be dishonest. To Ruskin and his followers (particularly William Morris), authenticity was paramount, reinforced by craftsmanship and the patina of age. Historic remains were to be carefully maintained to prevent greater loss, and repairs were to be conducted using complementary materials. These opposing approaches have shaped modern practice, and can still be seen in current conservation management charters and guidance.

The late nineteenth century also saw an increase in the number of nations introducing legislation to preserve historic places to protect them from change. In the United States industrialization presented an opportunity to reconsider how the country saw itself in the industrial world. Wealthy first and second generation migrants such as J. D. Rockefeller, J. P. Morgan, and Stephen Mather developed an interest in heritage. The recreation of the former capital at Colonial Williamsburg, Virginia, was supported by Rockefeller from the early 1920s, whilst Mather urged the creation of a National Park Service. Similarly there was an interest in the acquisition of heritage assets, with both J. P. Morgan and W. R. Hearst acquiring artifacts and buildings from both Europe and the United States. One outcome was that the City Council of Charleston, South Carolina became the first assembly to introduce planning and zoning regulations in 1929 in order to protect its distinctive colonial architecture and spaces.

As preservation legislation became established, nations created their own lists of nationally important heritage sites and created heritage bodies to manage those lists and sites. Ultimately a particular style of archaeology, repair, and presentation evolved emphasizing the individual site, and the authenticity of its fabric, history, and aesthetic, but presented in a scientific and scholarly manner treating the public as a passive recipient of a national narrative. The preeminence of American and European approaches to conservation ensured that this particular style of conservation management spread across the world through political, economic, and imperial

control and underpins present day approaches to CRM.

The high point of this approach is represented by the Venice Charter (ICOMOS 1964). This document set the international standard for the conservation of cultural heritage as something essential to human understanding, in common international ownership but focused on evidence, authenticity, and the historic place as a document to be “read” and preserved through the application of science. The Charter identified that heritage places had to be recorded and understood in order to inform change and established a common, international conservation practice to be adopted by anyone who chose to use it.

The idea of CRM as something distinct from archaeological research began in the 1960s and 1970s and one of its outcomes was that the limitations of the Venice Charter were soon revealed. The focus of this change was in the United States and Australia.

In the 1960s the Civil Rights movement and the growing profile of Indigenous political issues in the United States was matched by a similar growth in Indigenous rights in Australasia. At this same time archaeology was emerging from the shadow of antiquarianism to be a science in its own right, and one of its main areas of activity was in the field of human origins, including the archaeological and ethnographic study of Indigenous peoples. This brought archaeologists into conflict with the developing rights and sense of identity of Indigenous groups. Coupled with the increasingly scientific approach of archaeological method (termed “processual archaeology” because it sought to identify and establish universally applicable behaviors and processes) was a new relationship with developers whose work was to impact on buried archaeological sites (chiefly through the construction of long distance pipe lines), but also on “living” Indigenous communities.

There were two areas of disagreement. First, Indigenous peoples rejected the processual approach because it was imposed without consultation, presented a limited idea of “culture” and took the management of their own cultural heritage away from their community. Second, successive heritage legislative acts in the United States required that “significant” sites (including Indigenous sites) could be added to the National

Register, but failed to provide any definition of what “significant/significance” might mean.

In Australia, it was discovered that the Venice Charter was not sensitive enough to allow the informed management of Indigenous sites because its perspective was essentially western and scientific and did not accept alternative ways of understanding culture. As a result, the “Burra Charter” was published in 1979 (Australia ICOMOS 2013). The Charter provided new definitions for old terms, such as “conservation” and “restoration” and established new concepts. The term “place” was introduced in preference to “site” or “building,” in order to make stakeholders think beyond the limitations of fabric, and crucially, “significance” and “value” were made key to heritage management. The “significance” of a “place” was understood as the sum of the “values” attached to it. These “values” were in four main groups: esthetic, scientific, historical, and social. The outcome of developments in the United States and Australia was that the management of the heritage “resource” became distinct from pure archaeology and a discipline in its own right.

CRM was adopted by practitioners in the United Kingdom where it was known as “rescue archaeology,” and as in the United States, a recognized process of assessment of sites was to develop, primarily based around desk-based assessment (literature and map surveys), geophysical survey, archaeological evaluation to test or “ground truth” the geophysics and then redesign of the proposed development or full excavation as ways of “mitigating” the impact of the proposal. In the United Kingdom as in the United States, CRM/CHM work is undertaken commercially, whereas in other parts of Europe, France for example, the state plays a greater role in the initial assessment of the proposed development site. Initially both CRM and “rescue archaeology” provoked considerable disagreement between the research and commercial arms of archaeology. The research side considered CRM to be “bad” archaeology because it was fast, unfocused, and commercially rather research driven, while the commercial side of archaeology considered contemporary archaeological research to be irrelevant, elitist, and slow to develop new archaeological techniques.

Issues

From being a discipline surrounded by controversy, CRM developed into a term that covered both professional practice and research/theory, but there is now recognition that the term CRM should be applied to the suite of professional practices only, while “critical heritage studies” is the related field of academic and research enquiry.

The recent changes in heritage thought have all moved towards promoting inclusiveness, participation, and cultural difference; putting people before fabric. The principal heritage management approach is termed “values-based,” because it adopts the main tenets of Burra, but it is not clear whether the potential of a “values-based” approach has been realized.

One outcome of the distinction between CRM/CHM and critical heritage studies is a widening gap between theory and practice. Because CRM/CHM is largely defined by a commercial imperative to consider only sites under development, there is a sense that “heritage” can be defined and quantified in the manner of a material “resource.” Heritage can be “used,” notably for tourism, and by extension the economy, but heritage theory considers heritage as limitless: each generation leaves its mark on the world but offers its own interpretation of what went before. Therefore the possible interpretations of a place, such as Stonehenge, Wiltshire, England, or Mesa Verde, Colorado, United States, continue expanding. In this sense archaeological sites, for example, never diminish in number because society makes “new” sites. This presents a considerable dilemma for CRM/CHM as policy and practice are not able to deliver current ideas because the existing legal and bureaucratic heritage process has not matched this new understanding.

In order to address concerns about lack of research focus CRM/CHM is increasingly supported by predictive modeling to identify where archaeological deposits are likely to be found and research frameworks that identify what is archaeologically significant about particular regions and subregions, thereby allowing focus on particular research questions. This change in practice has eased disagreement within the archaeological profession because the new understanding of

where sites might be has given greater context to research archaeology.

However, the manner in which this expertise is used remains under close academic scrutiny, particularly the manner in which practitioners define and attribute “significance” and “value” to places. CRM can be understood as an exercise in power relations, with the manager having all the power because legislation and policy have made them “responsible” for decision making. An alternative argument proposes that the resource manager should be seen as a “facilitator”—someone who draws out the many meanings and associations attached to places.

The continued analysis of the role of expertise has led some to question the effectiveness of the values-based approach to CRM. Some consider that the problem lies in the attitudes and role of the practitioners applying an “authorized heritage discourse” or AHD (Smith 2006). The AHD is that range of practice, guidance, and legislation that privileges cultural institutions, historic fabric, authenticity, age, attribution, and connoisseurship. Contrary to the AHD is an approach to heritage that acknowledges difference, cultural diversity, participation, and community, seeing heritage as “process” rather than “product.” “Heritage” is about the dialogue between past and present, not lists of nationally important places.

The way in which places are identified as heritage assets remains contentious. Many nation-states have their own designation system for identifying individual sites, places, or landscapes as nationally important, assuming that there is an agreed “national story.” An opposing view argues that the identification of individual sites is an expression of the AHD because it favors a limited range of values with many places or themes (gender, for example), not part of a “mainstream” narrative. One of the weaknesses of the individual site approach is that it creates a polarity between the “iconic” and the “everyday,” whereby values are skewed towards the iconic, ignoring those elements of place that make it human and personal. Allied to this is the idea that the “characterization” of a place offers a more plural approach to the understanding and management of the cultural heritage.

“Characterization” (Fairclough 1999) is essentially a mapping exercise looking at the historical

depth of a place and can be applied to any area, from an extensive landscape to an urban backland. Characterization considers that all places are valued by someone, are all cultural products and culturally perceived and therefore places should be considered “value neutral.” A second stage in characterization is wide consultation on the identification of the values attached to the elements that make up that place. The aim is that the management of places should balance the iconic and the everyday, and thus be more sustainable because it better reflects an often unspoken sense of place.

Although the condition of important international heritage sites provoked the creation of many conservation charters, the idea of World Heritage designation has generated concern. While the imbalance between the high numbers of World Heritage Sites in western Europe and the smaller numbers in other parts of the world is clearly recognized, of greater concern is the way in which World Heritage designation is taken as an assumption that tourism and income growth will follow. Analysis of this expectation and the complexity of the relationship between tourism, authenticity, and heritage management are major topics in critical heritage studies, because they raise the issue of the role of CRM expertise but also the narrow and frequently contradictory content of many conservation charters and guidelines.

Post-conflict reconstruction and post-disaster recovery are established themes in CRM, particularly since the collapse of the former Yugoslavia. Conflict has focused on community and ethnicity and made cultural heritage sites, both the iconic and everyday, legitimate military targets. However, CRM practitioners and academics are split between those who negotiate with and advise the military before and during conflict about cultural matters and those who believe that greater consideration and commitment should be given to postwar reconstruction. The core of this difference is the argument about heritage privileging the authenticity of fabric, the ancient, and the iconic as opposed to heritage being about people and the provision of support for the rebuilding of communities and giving those communities the opportunity to reconstruct their own heritage places in their own time.

Future directions

Questions about who heritage is “for” remain a crucial theme in CRM. In response practitioners recognize that CRM has to become more plural and participatory but has to counter the conservative nature of the conservation discipline and practice.

Public participation in heritage activities, and specifically archaeological excavation, could be seen as something socially, physically, and mentally beneficial for people rather than being something to extend knowledge. Many CRM professionals would find this incompatible with developer-led work where site safety and commercial sensitivity can be subject to legal agreement. One alternative is that nonprofessionals could become more involved in the management of undeveloped heritage places, applying the skills from their own experience under the guidance of CRM professionals. Experience in the United States has demonstrated the vitality of local and charitable groups and could be extended beyond the usual “address book” of those committed to heritage to embrace other communities.

Perhaps the two most interesting areas of research are those at opposing ends of the cultural heritage spectrum: the concept of “living heritage” and the potential of digital heritage. Much of the new work on “living heritage” is being directed by ICCROM (ICCROM 2016), but also includes new work promised in India. Also known as a “people-centered approach,” living heritage recognizes that people are connected to their heritage in complex ways and are best able to manage their own heritage. What this means in practice is less clear, but the potential for shifting the management of cultural heritage from practitioners to communities is considerable.

The possibilities of digital heritage have yet to be realized, as they embrace both practical applications and the fundamentals of CRM. Digital approaches to survey and recording offer speed, accuracy, and detail but also present the ability to “look” through material previously considered a hindrance to analysis. Dramatic changes can be anticipated in the presentation of cultural heritage, from the use of dedicated apps offering layers of interpretation to a greater ease of communication between heritage communities. If living heritage is an anticipated area of growth,

and the existing focus on community and values continues, digital applications offer the ability for peer and community groups to talk to and learn from each other—across the World—without recourse to “official” heritage practitioners. The possibility for a revolution in “bottom-up” heritage practice is real and could redefine professional practice and the role of expertise.

Designing and Co-Creating Heritage

JONATHAN WESTIN

University of Gothenburg, Sweden

To communicate heritage, both tangible and intangible concepts must be not only interpreted but also expressed. Heritage is in this way performed, either directly or through representations and reconstructions—an act that solidifies the interpretation by giving it form and purpose. While heritage could be described as a set of values and understandings, not merely places, monuments, and artifacts (see Smith 2006), it is through the communication of heritage that meaning is collectively created. These expressed interpretations of artifacts or customs permeate society and thus play a pivotal role in a very active negotiation process, which serves to construct the meaning of heritage.

Co-creation shares a philosophical background with public archaeology and citizen participation, a mode of practice that encompasses outreach, education, and public interpretation and representation. However, public archaeology inherently leads to an asymmetrical power relation; the act of granting the public the limited power of participation both cements the scholar as instigator and gatekeeper and accentuates the public's lack of agency and resources. In contrast, co-creation describes a rhizomatic process, defined through a decentralized approach to heritage whereby the public is not directed by scholars but constitutes instead a creative force that shares the responsibilities of defining, caring for, and using heritage (Bollwerk, Connolly, and McDavid 2015).

As a process, co-creation can occur both at a community and at a societal level. At a community level, by engaging in dialogue with stakeholders, one can make a more diverse set of voices be heard. Stakeholders are not limited to those that are directly affected by a decision, but may also include those that perceive themselves

to have an emotional stake in a given place, artifact, or custom. By engaging a larger community of stakeholders, you pave the way for finding sustainable approaches to the management and development of heritage sites and memory institutions. This requires an organic approach to heritage, one that both empowers local industries and finds renewal in local initiative. To achieve this, heritage institutions should not stand outside society or dictate goals but should instead conduct an active dialogue with the public and develop a heightened sensibility to the unique situation of a community. By giving artifacts, monuments, or traditions a meaning for the local citizens, preservation can serve as an integrated part of the area's development. This sentiment is echoed in much of contemporary heritage practice, which has experienced a shift from a strong focus on material artifacts to a kind of preservation that also concerns itself with narratives and sociocultural contexts (Malpas 2008). However, this shift should not be seen as an abandonment of the material for the immaterial, since even immaterial culture is tied to materiality.

At a societal level, co-creation is not always expressed, or even thought of as such, as the processes that function to shape how heritage is used and expressed are not explicit. Instead, they are integrated into the visual design and communication of heritage. As a stepping stone toward communicating what heritage is, we make use of representations of artifacts and customs. In doing this we are bringing the public together with professors and students, museums and heritage institutions, and filmmakers, game makers, and other commercial initiatives. The actants of this assemblage are enrolled, either directly or indirectly, in the project of co-creating a shared representation of heritage. While far from always originating in academia, this is a formative process influenced by the techniques and symbols involved in the practical procedures of making a representation. The translations that these procedures bring about shape scholarly and popular visualizations alike. In fact one cannot separate popular representations from the world of science, since these representations create

DOI: 10.1002/9781119188230.saseas0166

ideas about the past and cement those ideas in society, of which the scientific community is a part (Moser 1998). However, *despite* the fact that their impact is not confined to popular culture but shapes our understanding of heritage, the practical procedures and technologies involved in creating a representation have traditionally been treated by nonpractitioners as no more than a string of intermediaries—processes that carry an idea unchanged—and not as a network of actants far from neutral in their practice of co-creating what heritage is. However, as evidenced by those illustrators and co-creators who are making their voices heard both through academic publications and through contributions to major academic projects, an idea is shaped by the minutiae of the procedures that give it form.

As visual and multisensory representations of culture and heritage are often the tools of politics and ideologies and make up both identity and nationality (Ashworth, Graham, and Tunbridge 2007), these processes have a great impact on what heritage is perceived to be, whom it belongs to, and how it is represented. An understanding of the processes through which society designs and co-creates these representations of heritage is crucial, since such processes are often located at the junction between the researcher and the public. Positioned in such a way, the communicative conventions that these representations use form a large part of the public's grasp of heritage, while they limit the scholars' ability to express new results in an unmediated way. Indeed, heritage is what we *collectively* represent it to be, regardless of whether we have been invited or not. The way we interpret and represent our material artifacts—and how we give strength to those interpretations through narrations, visualizations, and sociocultural connections—shapes us.

Designing for transparency: giving heritage a meaning

For an archaeological visualization to be meaningful, it must take risks but still be firmly grounded in established ideas. It must operate according to culturally accepted rules, moving

a couple of inches beyond the borders of absolute fact, to fill in the blanks and create a whole (Ammerman 2006). Therefore a visualization is best viewed as a contextualization of an interpretation; lost materiality is replaced to create a whole and a scene is designed that communicates a social context. It is therefore not a visual representation of the original artifact but a visualization of one of many of its interpretations; and, as such, it is a creation as much as it is a reconstruction.

Scientific visualization, as a method of communication rather than personal notation, emerged in the fifteenth century. By being translated into drawings, findings made during expeditions could be brought back home, shared, and analyzed. In the nineteenth century the reconstruction drawing, which was used to place the findings in a context, gained ground as a technique through which to express interpretations and communicate relations (Moser 1998). This development was echoed in a steady increase in the practice of physical, material reconstruction of monuments and sites. During the twentieth century this practice gave rise to a number of charters drafted to offer counsel: the Athens Charter in 1931, the Venice Charter in 1964, the Florence Charter in 1981, the Dresden Declaration on Reconstruction in 1982, the Nara Document on Authenticity in 1994, and the Krakow Charter in 2000.

The charters argue that reconstructions raise concerns of historical validity, as they present persuasive and strong interpretations that are almost impossible to “unknown,” while at the same time turning the process of their construction opaque. This is no less true for digital reconstructions. Our heritage is increasingly experienced as a virtual heritage, a space consisting of representations. Three-dimensional scanning through photogrammetry and laser, virtual reality, augmented reality, photorealistic computer graphics, and interactive displays—all these are technologies that have started to shape the professional field. While advanced digital documentation and convincing visualizations used to be the mark of grand initiatives such as Rome Reborn, Catalhoyuk, and Vulci 3000, an increasing number of smaller projects have made 3D scanning and modelling part of their professional workflow. While being a synthesis of

information, a reconstruction, whether physical or digital, might also be described as a dialysis, as it separates the unwanted or unknown from the construction and reduces complex associations and interdependencies to an ordered whole.

However, the generally used definition of reconstruction as the representation of a lost physical reality ignores the active process of making a reconstruction—and this applies in equal measure to physical and to digital reconstructions. The *act of reconstructing*, closer to the definition of reconstruction as an action or process rather than as a thing that has been rebuilt, is a process through which it is possible to assemble stepping stones for other processes and actants, which leads to insights about sources, contexts, and places otherwise overlooked. As an active process, the reconstruction is both a product and a means of productivity, as the practice embodies a transformative dimension. Hence, while reconstruction is a visual representation practice, not only is it a crucial step in the dissemination of results; it also plays a central role in the scientific process of developing theories. However, to design the past is never a neutral undertaking, even when this is part of a scientific process: by default, certain *properties* are inscribed into the design itself. If the interpretation is allowed to become a part of the idea of the place, these properties are made durable by being translated into a seemingly material form.

As a bundle of both tangible and intangible parts, heritage is, in the words of Neil Silberman, an “ever-changing array of objects and symbols, a complex mosaic of artifacts, images, and customs, that demand our attention and demand that we give some meaning to them”; by contrast, the past is a lived reality that survives only in fragments and can only be experienced in retrospect (Silberman 2008, 82). Arguing that we can never re-create the past as it actually was, with a sense of uncompleted presentness and uncertain expectation, Silberman states that any visual representation of the past is from the outset bound to be lacking. This implies that there can be no definite representation or description, no design that encompasses the entirety of this construction, as there are always new perspectives, changing alliances, and neglected stakeholders

to take into account, and all of them challenge our grasp of the concept and make it grow. Likewise, as heritage is made up of intangible traditions and social history as much as of any physicality, the challenge lies in also recognizing the activities that *surround* a custom or an artifact.

The future of designing heritage

The strength of a visual representation is its ability to activate our senses; it translates a technical language into a framework to which all parties can relate. However, this strength may also be used to establish an interpretation as a final truth rather than as a hypothesis. Thus a representation can isolate us from the scientific work, since its strength lends it a preferential right of interpretation, even in cases where the scientific basis of the representation has been altered or deemed false, or when it simply conveys a more diverse set of interpretations. It becomes a conscious part of the public’s notion of a subject and forms its own basis in popular culture, ensuring a widespread effect. Hence a representation is not neutral but occupies the same mental space as the material remains, shaping both how we collectively perceive them and how we expect them to be presented to us. Brought on by the inseparable activities of heritage manufacturing and tradition consumption, this creates a reverse flow of cultural capital (Alsayyad 2008). In consequence, our understanding of heritage is shadowed by our representation of heritage—a representation whose stakeholders and co-creators are numerous and whose sociocultural ties need to be considered when new representations are created.

Archaeologists have always wrestled with issues of representation, but the emerging photorealistic digital visualizations of the last three decades have accentuated these issues; through their use of realistic-looking shadows, textures, and perspective, the photorealistic representations lend the interpretation all the attributes of a convincing physical materiality, which conveys a deceptive feeling of certainty (Shapiro and McDonald 1995). This demands greater responsibility from museums and scholars: they must

actively rethink the way they make use of images in their communication, since an unchallenged interpretation, incorporated into a large body of knowledge drawn upon by others, risks becoming a fact.

A reconstruction moves us simultaneously farther away from and closer to the primary sources upon which the reconstruction is built: *away* from the sources, as they are the result of an interpretation and, as such, are perceived by many scholars as losing the inherent validity of the material remains upon which they are based; yet *closer* to the sources, since a reconstruction can bring those to life and place them in a context where further theories and hypotheses can be explored.

All scientific work has a communicative aspect, where thought and theory are dressed in visual form. As reconstruction processes often lack transparency and may cement, for the recipient, interpretations that become hard to challenge later on, recent studies in the visual communication of digital reconstructions have explored different approaches to communicating the uncertainty, rather than the certainty, of an interpretation. The methods have ranged from systems for computing reliability through fuzzy logic to visual cues incorporated in the model itself, such as conflicting interpretations and color grading. The majority of these studies concern themselves with developing techniques through which the past can be represented as “correctly” as possible—the translation from findings to reconstruction is done in a neutral way, so as to not add any ungrounded interpretations, colored by social interaction or speculation. However, the design of visual representations should also be seen as both an interpretational and a creative practice.

New methods need to be developed that should offer inroads into questioning a visualization rather than making the audience accept it, and that could make the translation from idea to representation less of a finality and more of a dialogue—the past being presented as unsettled, as it is in the notes of the archaeologist and on the drawing board of the artist. As cultural properties derive from an artifact’s or a site’s contact with the functions of social interaction, past and present, the interpretation

of this contact must be performed and presented in a transparent manner, leaving a track of symbols and data that tell a more complete story.

Experts and Stakeholders

L. HARALD FREDHEIM

University of York, UK

Introduction

For long an arena of “expert” engagement and control, heritage in the past few decades has seen a growing concern to draw in “stakeholders.” Experts are traditionally defined by their formal qualifications and knowledge, their expertise, and are very often paid professionals. Stakeholders are defined by their interests (whether place-based, community-centered, or thematic) and often by ownership in one sense or another. The relationship and difference between the two is a fraught area, and the drive for more engagement and participation in heritage is bringing underlying issues around experts and stakeholders to the foreground, which have major implications for both heritage practice and theory. This piece attempts to provide an international overview of theory and practice relating to experts and stakeholders in a heritage context, but is inevitably shaped by the author’s more in-depth knowledge of developments in the United Kingdom and published literature in English.

Heritage professionals in many parts of the world are increasingly concerned with encouraging members of the public to interact with heritage. Innovative approaches to interpreting (see *HERITAGE INTERPRETATION*) and presenting heritage to the public utilize ever more diverse ranges of media, including social media and immersive visualization technologies such as augmented reality (see *AUGMENTED REALITY*). Concurrently, developments in heritage management (see *HERITAGE MANAGEMENT*) call for professionals to encourage public participation in identifying and looking after heritage.

In the modern history of heritage, issues of experts and stakeholders have largely been

approached implicitly, but the questions of valid forms of knowledge about heritage that underpinned the discussions around the formation of the Nara Document on Authenticity in the 1990s (Larsen 1995) have become explicit in recent heritage charters. The Faro Convention (see *FARO CONVENTION*), for example, connects heritage and human rights (see *HERITAGE AND HUMAN RIGHTS*), giving rise to entire scholarly volumes on heritage expertise (Schofield 2014). Questions of expertise now sit at the center of the growing body of critical heritage studies, in which critical theory (see *CRITICAL THEORY*), and its foregrounding of politics, power, inequality, and exclusion are applied to heritage. Experts and stakeholders are therefore not simple distinctions between heritage professionals and the public, but contested value-laden terms that privilege selected interpretations of heritage, perpetuating existing power structures.

Defining experts and stakeholders

An expert is widely understood as an individual with superior knowledge or skill in a certain area; this superior skill or knowledge is referred to as expertise. Experts are often regarded as authorities on their subject and as such can hold considerable power. This power may be freely given in recognition of perceived expertise or imposed through legislation by authorities. A stakeholder is a person, group, or organization with a stake, understood as an interest or a claim to something. While experts are identified by virtue of their perceived expertise, stakeholders tend to be self-selecting and involve themselves in order to represent their interests. Stakeholders and their interests may or may not be recognized by decision makers, yet stakeholders are not employed or compelled, but choose to assert their interests.

With regard to heritage, the term “stakeholder” is almost exclusively used in the context of decision making in heritage management.

Nevertheless, many of the functions performed by cultural organizations operating on behalf of the public, such as public museums, are based on an understanding of members of the public as stakeholders. The perceived duty to present and display collections and sites accompanied by the results of expert research, highlights the sense that heritage does not belong to experts, as further demonstrated by the growing pressure to repatriate (see REPATRIATION) collections, especially in postcolonial contexts. New modes of engagement that invite audiences to interact with heritage more directly, coupled with developments in heritage ethics (see HERITAGE ETHICS) that emphasize respecting cultural diversity and legitimize nonwestern understandings of heritage (see HERITAGE: NONWESTERN UNDERSTANDINGS), are blurring established distinctions between experts and stakeholders.

Stepping beyond the complex issues of ownership, current heritage management literature and practice predominantly follow values-based approaches. These approaches are based on the premise that heritage is conserved and used because it is valued, and that decisions about heritage should be made on the basis of as comprehensive an understanding as possible of its values and significance (see VALUE OR SIGNIFICANCE). As a result, stakeholder consultation is increasingly advocated due to the recognition that expert knowledge alone is insufficient to inform multicriteria decision making. The expanding range of what is considered heritage, from the monumental and aesthetically pleasing to include complex landscapes (see HERITAGE AND LANDSCAPES), the vernacular, and the intangible (see MULTIVARIATE ANALYSIS), is also prompting the search for expertise beyond established expert circles. Despite this, traditional distinctions between experts and stakeholders, and the authority awarded to each, have remained largely unchanged in practice.

As heritage management continues to advocate plurality and multivocality, archaeologists are increasingly having to justify the primacy given to archaeological knowledge and expertise. Their perceived position of privilege is under pressure from critical heritage scholarship, which seeks a different balance between experts and stakeholders. While archaeologists engaging with these critiques have argued that archaeological

experts working as heritage managers should consider themselves heritage managers first and archaeologists second, in an effort to treat fairly the various values attributed to heritage (Emerick 2014), others regard archaeologists as powerful stakeholders who have coopted heritage and doubt the extent to which archaeologists can divorce themselves from their disciplinary training and preference (Waterton and Smith 2009).

Reasons for engagement and participation

Heritage experts and institutions are increasingly required to demonstrate their relevance and value to society. As a result, boosting engagement metrics, such as visitor numbers, and diversifying visitor demographics are becoming more important. A growing number of scholars are conducting research to demonstrate the wider social significance of heritage (see HERITAGE AND SOCIETY) to pressing concerns such as sustainability (see HERITAGE AND SUSTAINABILITY) and wellbeing, and to develop more accurate metrics that capture the full range of ways in which people engage with heritage. Heritage practice and research is thus increasingly underpinned by a belief that active participation and engagement in heritage activities provides social and individual benefits.

Despite the potential benefits to participants, stakeholder participation in heritage is also promoted to raise the quality and capacity of professional practice. The management of heritage sites and collections in line with the standards of best practice promoted by monitoring institutions and policy is often not possible without the active support of local communities and volunteers. Most archaeological sites are not guarded when professional work is not ongoing and rely on the involvement of stakeholders for protection. Many smaller museums and remote heritage sites are similarly reliant on the voluntary initiatives of stakeholders. Larger institutions often also depend on volunteers to complete large survey, digitization, and simple conservation (see CONSERVATION) projects that would not be viable with paid professional

capacity alone. When budgets are stretched thin, discussions of appropriate distinctions between professional labor and voluntary contributions inevitably arise, relating to issues of both ethics and expertise.

Concerns with heritage ethics (see *HERITAGE ETHICS*) and the implications of their application to values-based approaches (see *HERITAGE AND VALUE-BASED APPROACH*) have highlighted the contested nature of heritage and contributed pressure to democratize and decolonize heritage, especially in postcolonial contexts. As a result, in countries like the United States, Canada, Australia and New Zealand, decisions about how indigenous heritage is conserved, studied, and displayed are more often made in consultation with, or entirely by, Indigenous stakeholders, and the employment of Indigenous experts in cultural organizations is becoming more common. The conventions of the Council of Europe have spread these ideas of democratization and local knowledge to Europe by advocating for the legitimacy of stakeholders' memories (see *MEMORY*) and perspectives on place and identity as valid forms of knowledge about heritage. An example is the European Landscape Convention, which calls for the involvement of stakeholders in every stage of heritage identification and assessment to aid decision making and the formation of policies.

Alongside demonstrating the relevance of heritage to society and increasing the capacity and quality of professional work, public participation in heritage activities is advocated to facilitate connecting people to their heritage. By actively taking part in community archaeology (see *HERITAGE AND COMMUNITY ARCHAEOLOGY*) and community heritage (see *COMMUNITY HERITAGE*) projects, participants can gain a new appreciation for the heritage they have interacted with. Arguably, it is through interactions like these that new attachments to heritage can be formed, thereby increasing their significance within a values-based framework. It may be hypothesized, following hierarchies of learning developed in pedagogy, that deeper engagement or more involved participation will lead to greater attachment.

Methods for engagement and participation

The range of methods used by heritage professionals to provide more immersive and engaging heritage experiences is becoming broader. This enables heritage professionals to draw on and develop the expertise of stakeholders, simultaneously strengthening the attachments to heritage of existing stakeholders, and facilitating the formation of new stakeholder attachments. Traditionally behind the scenes processes, such as conservation in museums, are increasingly made visible through panels, temporary pop-up exhibits, purpose-built conservation studios that allow visitors to observe professionals at work, and participatory conservation projects where volunteers are allowed to perform conservation tasks with supervision. Similarly, some museums invite community curators, where stakeholders are given the opportunity to create displays. The most visible changes in traditional heritage environments are perhaps the continuing adaption of new technologies to provide more realistic and immersive experiences, as well as the use of the Internet to facilitate virtual visits from the comfort of one's home.

While volunteering has a long history in archaeology and heritage, the rise of Web 2.0 technologies and the social web have created new cultures of participation that extend to the heritage sector (Giaccardi 2012). These new technologies and cultures both facilitate and demand the development of new interactive modes of public engagement and participation. One of the most significant new approaches is crowdsourcing, which allows anyone on the Internet to become a digital volunteer. Crowdsourcing has the potential to allow institutions to perform tasks of a magnitude beyond their professional capacity, such as transcribing texts and tagging images or videos to create, and facilitate searches within, digital archives, but it is also increasingly employed as an engagement strategy (Ridge 2014). Crowdsourcing is not unproblematic however. There can be significant costs of developing and supporting crowdsourcing programs, and there are concerns relating to the ability of digital volunteers to perform expert tasks, with linked

issues of data validity. There can also be problematic ethics of crowdsourcing arising from its exploitative nature when commercialized.

As stakeholders continue to be recognized as valid sources of heritage knowledge, heritage professionals are beginning to utilize a wider range of ethnographic and qualitative research methodologies (see *ETHNOGRAPHY AND QUALITATIVE METHODS IN THE FIELD*) to access stakeholders' expertise. These methodologies are often utilized in conjunction with various forms of coproduction, such as countermapping (see *COUNTERMAPPING*), participatory GIS, and codesign (see *CULTURAL RESOURCES MANAGEMENT*), as well as research philosophies such as participatory action research, which deliberately further blur the traditional boundaries between experts and stakeholders by advocating research *with*, rather than *on*, participants. Crucially, these approaches do not only democratize research processes and produce new forms of research data, but they are also immersive engagement activities that can facilitate the development of skills and a sense of community ownership of heritage (Jones 2017), thereby providing an effective mechanism for stakeholder development and facilitating stakeholder agency in caring for heritage.

Critical perspectives on participation

As calls for participatory approaches to heritage practice have become more common, critical analysis is moving from the promotion of participation as a solution to an emphasis on participation itself. While power may be shared with stakeholders by inviting participation, it can also be retained through this invitation by controlling and managing the forms participation may take. A growing number of scholars are highlighting the mismatches between the promises and realities of participatory practice, especially those practices that employ supposedly democratizing digital technologies. It is becoming clear that while participatory approaches may have the potential to democratize heritage, participation can be as exploitative as it is emancipatory, and

may in some cases be equally as likely to exacerbate issues of diversity and representation as to solve them.

A critical perspective on participation originates with the identification of power. While participatory approaches invite stakeholder involvement, stakeholders may have limited agency over the nature of their involvement and their contributions may not carry much weight. Tokenistic consultations where participant perspectives are not regarded highly enough to influence professional preference can breed distrust of professionals and disillusionment with participatory projects. Reports on more involved participation in museums from countries like the United Kingdom and Canada, such as projects where communities are invited to participate in curatorial activities involving collections from their own culture, may also build resentment, where controlled access reminds participants of the injustice of forced separation from their heritage and any participation on their part is felt to legitimize the institutions responsible.

Issues of power are also highlighted in less charged volunteering contexts because ethical concerns raised by digital approaches, such as crowdsourcing, are becoming more common in the heritage sector. Participatory projects tend to be more expensive and less efficient, and it is unclear whether projects can unproblematically be motivated by both a desire for inclusion and the need to balance budgets, especially at a time of declining budgets. In light of the belief that heritage is a public good and that heritage services should be for public benefit, the concern that participatory projects may be exploiting volunteers is especially acute.

This issue is compounded by the growing prevalence of volunteer positions requiring qualifications and of unpaid internships and of the lack of paid graduate employment opportunities in the United States, United Kingdom, and much of western Europe. It raises fears that paid employment in the sector is becoming available only to those who can financially afford to gain experience and exposure through unpaid activity, which also exacerbates the existing lack of diversity within heritage professions. There may be a danger of a salary becoming the most obvious distinction between an expert and a stakeholder.

Critical scholarship is also highlighting that while participatory approaches claim to be democratizing and diversifying heritage, stakeholders are self-selecting, and populist democratization of heritage through open calls for participation may therefore reinforce existing power structures and produce less diverse narratives. This danger is especially acute in contexts where the boundaries between public engagement activities and participatory research projects are blurred; self-selection bias is insignificant in one but crucial in the other (Tourle 2017). Such blurring of boundaries between experts and stakeholders, and between different forms of engagement and participation, calls for the renegotiation of roles and responsibilities, as well as the knowledge and skills required of heritage professionals.

Future directions

Established expert and stakeholder roles, responsibilities, and perceptions of expertise are actively challenged in contexts where stakeholder groups initiate projects and bring professionals in as they see fit. In many of these projects, the nature of the stakeholder-expert relationship shifts; professionals become participants in, rather than the driving force behind, collaborative ventures. The distinctive dynamic of these projects arises from their origin among stakeholders, allowing volunteers to take leading roles and remain decision makers even when working alongside paid professionals. While researchers are noting that successful community-led projects can be powerful sources of social innovation, less attention has been paid to how such initiatives can be encouraged and supported without disturbing their dynamic. Similarly, while current research is beginning to address what makes public participation feasible and productive in different circumstances, less is known about how contexts initially less conducive to collaboration can become productive sites for participatory initiatives.

The changing dimensions of heritage engagement and participation are revealing the need for a wider range of forms of heritage expertise. While it is clear that heritage professionals are

increasingly called on to function as facilitators of collaborative ventures, this does not mean that traditional forms of expertise are no longer relevant or that professionals should set their technical expertise aside in order to adopt the role of an impartial facilitator. Arguably, the legitimization of a wider range of forms of expertise is required, not the devaluing of established experts. It should not, however, necessarily be assumed that established experts are the only potential source of these new forms of expertise, nor that they are the best candidates to fill the role of facilitator. It is through the negotiation of changing roles and responsibilities that the future nature of “experts,” “stakeholders,” and their relationships will be determined; these negotiations are ongoing in heritage scholarship and in heritage practice.

Faro Convention

NOEL FOJUT

Consultant, UK

Background and context

The Faro Convention (hereafter “Faro”) is the most recent of a number of Council of Europe (CoE) Conventions dealing with cultural heritage. Its tone and content reflect changes in perceptions about cultural heritage that have been inspired among heritage experts and political decision makers by key social concerns of the late twentieth century. These concerns include recurrent economic crises, globalization, the shift to an “information society” with more leisure time for many citizens, social tensions arising from demographic factors (including large-scale migration), and concerns over quality of life. Faro—its formal title being the Framework Convention on the Value of Cultural Heritage for Society—sees Europe’s shared cultural heritage as having the potential to offer ways of mediating or mitigating these forces.

The Council of Europe is an intergovernmental organization founded in 1947 which seeks to agree and raise common standards within Europe on matters concerning human rights, democracy, and the rule of law. Except for Belarus, all countries within Europe are members—47 in total. CoE is quite distinct from the European Union, though all 28 current EU members are also members of CoE.

Framing

Emphasizing the importance of the “common heritage of Europe”—self-evidently a cultural heritage—CoE wished to make a strong association with human rights and with the fundamental freedoms for which the CoE’s primary mission is to act as a guardian—in effect, a “right to heritage.”

Faro’s technical roots lie in major changes in heritage discourse and practice, largely in respect of the built heritage although intangible heritage is not excluded. The previous decades had seen a shift in focus from elite items of (built) heritage significance for their own sake (intrinsic value) and towards the sustainable management of a much wider range of heritage sites, objects, and traditional practices seen as assets to be used to benefit society at large (use value). The CoE’s aim in drafting Faro was to offer the approval of CoE, Europe’s senior intergovernmental deliberative forum on culture, for this new “democratic paradigm,” setting out guiding principles and offering guidance on how social value might legitimately be derived from heritage through sustainable use.

It was implicitly acknowledged that the traditional European model of state-funded protection and conservation of heritage was no longer sufficient, and required a new model characterized by “greater democracy, strengthened citizen participation, and better governance based on more open, reactive, and transparent institutions.” This shift towards a more open, democratic approach to defining and managing heritage reflected wider movements in practical politics away from state authoritarianism; it was accompanied by a preferred partnership model in which governments are no longer seen as the sole guardian of national heritages. Pragmatically, it recognized that (faced with an increasingly wide spectrum of social responsibilities) governments were neither best placed nor able to afford to intervene across the whole spectrum of heritage, the scope of which had expanded in the course of a century from a very few famous and ancient sites and buildings, to include much of the world in which Europe’s citizens live.

Drafting

The Convention was drafted during 2004 by a group of experts nominated by national culture ministries. The Group reported to CoE’s Steering

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0239

Committee on Culture, Heritage and Landscape, and was supported by a small secretariat led by the present writer.

The expert group began with certain core concepts taken as given. The organizing principle would be cultural heritage as an asset to be valued for the practical use which society can derive from it, rather than as a burden to be borne for its asserted inherent value. Associating this with the idea of rights and the balancing responsibilities of individuals, communities, and civil society, was likewise a given, as was the idea of a participatory democratic approach.

From the beginning of drafting, the Convention was intended to be very different from the Council of Europe's earlier heritage treaties, the Granada and Valletta Conventions on the preservation of the architectural and the archeological heritage respectively. It shares themes however with the European Landscape Convention (the Florence Convention), including recognition of significance in the heritage of the everyday, an emphasis on participative action, and a multi-disciplinary approach. It was also deliberately different in its focus from the UNESCO World Heritage Convention (which deals with "elite" heritage sites only) although more in accord with UNESCO's Convention on Intangible Heritage.

CoE and many commentators have asserted that the important philosophical innovation of Faro was to place people and human values at the center of an enlarged and cross-disciplinary concept of cultural heritage. The phrase "people-centered" is widely used about Faro. Faro explicitly shifted heritage discourse towards human rights discourse, asserting that everyone has a right to engage with the cultural heritage of their choice, but also that such rights entail responsibilities. By coupling this with the concept of democratic participation in all heritage-related processes, it sought to ease the burden on governments by sharing responsibility for heritage protection across civil society.

The Convention itself

Writing international instruments is always a process of collaboration and compromise. For Faro

(Council of Europe 2005a), key compromises lay in defining terms, not least "cultural heritage." The Explanatory Report to the Convention explores these issues in some detail (Council of Europe 2005b).

Faro adopts a very broad definition of cultural heritage, which includes tangible and intangible aspects, as well as interactions. To date, this remains the broadest definition of cultural heritage in any major international instrument:

cultural heritage is a group of resources inherited from the past which people identify, independently of ownership, as a reflection and expression of their constantly evolving values, beliefs, knowledge and traditions. It includes all aspects of the environment resulting from the interaction between people and places through time

Core to Faro is a second definition, asserting that heritage acquires value through collective action by communities (rather than by expert-led valuation):

a heritage community consists of people who value specific aspects of cultural heritage which they wish, within the framework of public action, to sustain and transmit to future generations.

A specifically European dimension is added defining the common heritage of Europe as:

all forms of cultural heritage in Europe which together constitute a shared source of remembrance, understanding, identity, cohesion and creativity, and ... the ideals, principles and values, derived from the experience gained through progress and past conflicts, which foster the development of a peaceful and stable society, founded on respect for human rights, democracy and the rule of law.

It is important to note that this explicitly positions Europe's cultural heritage as a force for progress and simultaneously asserts that the vision of a peaceful and equitable society is itself part of Europe's heritage—although Faro does not claim any particular European uniqueness for this positive vision.

Having defined its terms, Faro sets out the concept of rights to heritage and their accompanying responsibilities: "everyone, alone or

collectively, has the right to benefit from the cultural heritage and to contribute towards its enrichment (and) the responsibility to respect the cultural heritage of others as much as their own heritage.” These rights may have limits, and Faro cautions that the “exercise of the right to cultural heritage may be subject only to those restrictions which are necessary in a democratic society for the protection of the public interest and the rights and freedoms of others.”

As a creation of an intergovernmental body, Faro is addressed to national governments. Those that ratify the Convention formally agree that the above rights exist. They also agree to formulate integrated strategies to facilitate the implementation of the provisions of this Convention and to take specific actions, such as to recognize the public interest associated with cultural heritage, to enhance the value of cultural heritage through identification, study, interpretation, protection, conservation, and presentation, and to have appropriate national legislative provisions for exercising the right to cultural heritage. They also agree to foster an economic and social climate which supports participation in cultural heritage, promote cultural heritage protection as a central factor in sustainable development, cultural diversity, and contemporary creativity.

Specific fields of policy making activity where Faro posits these general principles will bear fruit are in:

- benefiting from dialogue (how heritage is presented, how different interpretations and differing views are accommodated equitably, how better knowledge can promote mutual understanding, and how cultural heritage can play a role in all kinds of education and training);
- using heritage to add value to quality of life issues (economic, political, social, and cultural development), wider environmental management, and social cohesion;
- pursuing sustainable use and management; and
- exploiting the economic potential of heritage.

Faro requires signatory states to recognize the principle of shared responsibility for cultural heritage and public participation, by acting in four main areas:

1. Integrated, well-informed, and innovative cooperation—promoting approaches which respect voluntary initiatives and drawing into collective action public authorities, experts, owners, investors, businesses, nongovernmental organizations, and civil society more generally.
2. Access to and democratic participation in heritage—encouraging universal participation, reflection, and debate, taking into account the value attached by each heritage community to ‘their’ cultural heritage, recognizing the value of the voluntary sector as both partner and critic.
3. The inclusion of cultural heritage in education at all levels, in its own right, and as a fertile source for studies in other subjects—strengthening links between heritage education and vocational training, encouraging interdisciplinary research, and promoting all forms of knowledge exchange.
4. Harnessing the information society, by encouraging initiatives to promote content quality and linguistic and cultural diversity, and by seeking to improve access to information.

The Convention does not contain any provisions for enforcement—signatories must self-monitor, encouraged by NGOs and international associations. There is no “European Court of Heritage” to hold countries to account.

Progress since Faro was launched

The broad scope of the Convention, which led to it being entitled a *Framework* Convention, means that it is relatively easy for states to show that they are undertaking actions which are in the spirit of Faro. In many countries, the idea of “doing Faro” has become accepted shorthand for a participatory approach to heritage with shared responsibilities and mixed public and private resourcing.

Early ratifiers were predominantly countries whose independent existence had relatively recently been reestablished or redefined, principally in the former USSR and its associated bloc, and in the former Yugoslavia. In such

countries, cultural heritage as a contributory element of national identity tends to enjoy a high political priority. (The two early exceptions to this observation are Portugal and Norway, both of which were heavily involved in the drafting process at steering group and expert group level.) The Convention gained the necessary 10 state ratifications for it to come into effect in ratifying countries in 2011, but since then it has only slowly gathered additional signatories. As of early 2017, 17 of the CoE's 47 member states have ratified it, and a further five have reached the first stage of signing it (Council of Europe 2016). It may be doubted whether some countries will ever ratify it, especially amongst the larger countries of "old" Europe, not necessarily through lack of agreement with its principles, but through government claims that those principles are already widely accepted and acted upon.

CoE continues to promote the Convention, both as a source of inspiration and guidance and also as an instrument to be ratified. However (in the spirit, it could be argued, of the Convention's own participative ambition), the general idea of "Faro actions" has taken on a life of its own. In recent years CoE has focussed more on badging and endorsing a range of international activities as Faro-related than on encouraging additional ratifications.

Heritage and Community Archaeology

CARENZA LEWIS

University of Lincoln, UK

Heritage and community archaeology

Definition, principles, and scope

Community archaeology is archaeology by, for, about, and within contemporary communities, in which members of the public are involved in initiation, design, consultation, execution, management, interpretation, and presentation of investigations into their tangible heritage. Community archaeology lies at the intersection between public archaeology (see PUBLIC ARCHAEOLOGY) and community heritage (see COMMUNITY HERITAGE), but is focused specifically on the connection between communities and archaeological remains, whether held in museums, buried underground, ranged across landscapes, or surviving as upstanding buildings still in use.

The principle defining and underpinning community archaeology is that it is archaeological activity which simultaneously benefits archaeological remains, people, and communities. The justification for the first case is that *tangible heritage* will be better cared for by people whose understanding, empathy, and appreciation has been increased by engagement, while archaeological interpretation will benefit from new ideas from people from different backgrounds. In the second case, *people* will benefit by acquiring new knowledge, skills, aspirations, interests, social connections, and enhanced sense of connection with their place. Thirdly, *communities* will benefit as the process and outcomes of collective engagement with archaeological activities and discoveries contributes to place-making, strengthens social bonds, builds social capital, and boosts local economies.

The definition of community archaeology is not without difficulty, not least because “community” is itself a mutable construct (Isherwood 2012). It is often conceptualized spatially as a group of people connected by living in the same place, but such a definition may not suit people living outside the community but with a connection with it, or people who have little or no connection with people they live near. Furthermore, communities can define themselves by other criteria such as gender, economic status, occupation, hobbies, religion, ethnicity, sexuality, education, or health status. Complicating matters even further, while the term “community” can be inferred to represent a homogeneous group, any community will always contain internal differences, as people are multifaceted and will share different aspects of their identity with different groups of people. However, the essence of community archaeology is its focus on communities, however defined, and its terminological “fuzziness” in fact provides useful plasticity for a growing discipline to explore new directions.

The scope of community archaeology has been extensively debated, and while a broad consensus exists that it should aim to bring people and archaeological investigation together to the mutual benefit of both, it has proved more difficult to agree scope or remit more precisely. Faulkner and Moshenska, writing in *Public Archaeology* nearly a decade apart (in 2000 and 2008 respectively) both reflected the view that a project can only really be termed “community archaeology” if it is instigated and driven by its community. On the other hand, several contributors to the seminal 2002 *World Archaeology* issue devoted to community archaeology presented externally instigated projects in which communities have a secondary, mediated involvement (e.g., advising on designing a museum). Agreement has not even been reached as to whether precise definition is desirable: this is advocated by those who believe this to be essential if the discipline is to be taken seriously, and rejected by others who consider the circumstances that the subject encounters to be so diverse that attempts

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0275

at definition will sooner or later prove either inadequate or counterproductive.

The morality of involving nonspecialists in archaeology at all has also been questioned. One argument holds that all archaeology should be “community” archaeology because the past is a collective asset and everyone has the right to connect with its physical remains. The countervailing view is that instrumentalizing archaeology to achieve any aim beyond simply protecting heritage assets or advancing knowledge of the past cannot be justified, as in setting other needs alongside those of the archaeological remains, as those of the latter may be jeopardized.

Difficulties can arise when there is potential for archaeology to have a negative impact on communities, which is possible in circumstances involving disputes over ownership of archaeological material (which may relate to sites, artifacts, or human remains), or when narratives derived from knowledge of the past are being corrupted to further political agendas or human rights abuses, or when livelihoods may be threatened by heritage protection measures. There are no simple answers to these questions because human societies are not simple, but ethical issues (see *HERITAGE ETHICS*) are always an important consideration when community archaeology projects are being developed.

Methods

Community archaeology is different from much other archaeology and from much other community work because it must respect both people *and* archaeology. Serving two masters is not easy, and assessing how to balance the degree of control exercised by archaeologists and non-archaeologists to ensure diverse aims are all met without damaging compromise requires careful planning, for which there is no simple formula: all sites and all participants differ in their needs and their capacity. There is consequently a wide degree of variation, both between schemes and within the same scheme, in how people participate: At one end of the spectrum volunteers may be restricted to simple routine tasks such as washing finds, at the other, volunteers may control every stage of project instigation, consultation, design, planning, execution, management, and reporting.

Whatever the situational context, community archaeology should be carried out to the highest archaeological standards, using methods and equipment for planning, fieldwork, recording, postexcavation and reporting most appropriate to meeting the archaeological aims (detailed in the “Field Methods” SAS entries), which should be detailed in the project design or written scheme of investigation. Similarly, community aims should be clearly identified and the methods used to achieve and evaluate these equally clearly elicited. Communities should be consulted at all stages, starting with project design. Members of the community should be able to participate as fully and autonomously as their knowledge, skills, experience, and abilities allow, while respecting the needs of others and of the archaeology under investigation. The whole team should work together respectfully and avoid an “us-and-them” division between professional archaeologists and volunteers. Everyone should have the chance to learn as much as they want to about the site and the project aims, and hear and give frequent updates about progress. Those in a supervisory or training role should be aware that volunteers will have knowledge and experience of value to the project, and endeavor to identify individual aspirations, needs, knowledge, skills, or interests so these can be met and deployed. Training and support should be appropriate and the pace of the project matched to the capacity of participants. Decision-making should be as democratic as possible commensurate with the need to meet identified aims, and should always be respectful of the opinions, feelings, and ideas of all who feel a connection with the project and its outcomes. The results of the investigations should always be shared with volunteers and with the host communities at all stages of the project in as many ways as possible to ensure wide access while evaluation of the outcomes should include community aims. The benefits of the project should be shared as widely and equitably as possible.

Conducted according to those principles, community archaeology schemes can educate, inform, inspire, and upskill participants while also advancing knowledge and understanding about the past and its impact on the present, enfranchizing volunteers and communities, developing notions of place and identity, and contributing to place making by advancing

and democratizing “insider” knowledge about the past.

Changes over time in the topic and its treatment

Community archaeology is a global phenomenon which has followed different but interconnected developmental trajectories in different countries. Before the twentieth century there were no professional archaeologists so all archaeology was in effect community archaeology, but involved very narrowly defined communities. In the United Kingdom “antiquarian” activity was largely restricted to gentry and aristocratic circles until the mid-nineteenth century when expansion of education and transportation encouraged the foundation of county archaeological societies whose members ran museums and carried out excavations. These communities, defined by a shared interest in archaeology, were numerically small and dominated by relatively affluent, educated males mainly interested in high-status sites. Participation broadened a little socially as local groups appeared in towns and rural parishes, accelerating in the postwar years as higher education and adult education expanded and the Council for British Archaeology (CBA) and the British Association for Local History (BALH) were founded in the 1940s. Although membership remained mostly middle-class, groups enthusiastically took the initiative in finding local sites to excavate and new academic interest in deserted medieval villages prompted some to explore past communities spatially more closely connected to the places they themselves inhabited.

In the 1960s and 1970s, growing interest in heritage and environmentalism encouraged and enabled county planning offices and many museums in the United Kingdom to appoint professional archaeologists to record, monitor, and protect archaeological sites, collaterally nurturing community engagement. Job creation schemes such as the Manpower Services Commission (1973–87) gave hundreds of unemployed people work on community archaeology projects such as Raunds (Northamptonshire) and La Grava (Bedfordshire), many commissioned specifically for this purpose. Museum archaeologists such as

Peter Liddle in Leicester published early technical guidelines for community archaeology and founded networked groups which still thrive more than 30 years later (<http://leicsfieldworkers.co.uk/>). The decades after World War II were the first golden age of community archaeology in the United Kingdom.

However, by the late 1970s the tide began to turn. UK government programmes were cut during recession and in many community groups the laborious process of postexcavation analysis began to outstrip the capabilities (or even lifespans) of some of their instigators. New techniques made excavation increasingly informative but also more specialized, complex, time-consuming, and costly, and by the end of the 1980s many professional archaeologists employed to protect the archaeological resource prioritized its preservation and saw excavation as a last resort, only to be carried out by trained and experienced professional archaeologists if sites were threatened by development. Opportunities and support for community groups to take part in excavation became more restricted, and their dwindling number became detached from professional archaeologists.

Communities elsewhere across the world were also frequently disconnected from their local archaeology. In countries such as Australia, Africa, the Middle East, and the United States, archaeological investigation had been introduced in the eighteenth or nineteenth centuries by colonial incomers with no connection to local communities: antiquarians interested in collecting “native” artifacts or unearthing classical or biblical remains typically either ignored local people or used them as laborers. With a few notable exceptions the situation improved little until the 1970s when, in response to wider political campaigns for recognition of the rights of indigenous people, across the world projects in America, Africa, and Australia began to offer different ways of working with local and descendent communities (Ucko 1983). In the United States at Ozette, Richard Daugherty excavated throughout the 1970s at the invitation of the local Makah tribal council, who retained a significant degree of control throughout the project, ensuring finds and records were retained locally in a purpose-built cultural centre. In Africa, Peter Ucko in the 1980s brought to

global attention politically motivated racist misinterpretations of indigenous archaeology produced in white-ruled Zimbabwe. In Australia, Shelley Greer and Susan McIntyre-Tamwoy developed a community-based approach to archaeological fieldwork in northern Cape York using ethnographic interviews and community workshops.

In the United Kingdom, Mick Aston's "Shapwick Project" exemplified participative community archaeology "about, by and within" local communities: hundreds of local people took part in archaeological investigations into the long-term development of this rural English village, with the results regularly reported to wider publics in diverse accessible local venues including village halls and local fetes. The project significantly advanced subject knowledge in final publications which included a 400-page "popular" volume formally dedicated to "the people of Shapwick, past, present, and future."

At the turn of the millennium, while frustration with the lingering gulf between members of the public and "official" archaeology remained (Faulkner 2000), progress was evident in the arrival of a new academic journal, *Public Archaeology*, soon followed by a special issue of *World Archaeology* dedicated to community archaeology in 2002. The latter highlighted the role of community archaeology in empowering local communities, and methodologies for achieving this were developed and refined, stressing the need for archaeologists to cede at least some of the decision-making to local or indigenous communities. In the United Kingdom from 2002, the Heritage Lottery Fund (HLF) did exactly that, explicitly directing increasing proportions of the hundreds of millions it granted each year to projects proposed by communities and involving public participation (Maeer 2017). By 2010, Suzie Thomas' survey for the Council for British Archaeology showed that around 215,000 individuals belonged to more than 2,030 active archaeology groups in the United Kingdom, 41 percent of which were involved in excavation with others carrying out fieldwalking, photographic recording, attending talks, and heritage lobbying (Thomas 2010).

In the second decade of the twenty-first century, many of these community archaeology groups have become increasingly autonomous, helped by initiatives such as the joint HLF and the

Arts and Humanities Research Council *All Our Stories* scheme which in 2012–13 put community groups firmly in control of proposing project ideas and controlling budgets, which allowed them to buy in expertise and training to suit their aims and needs. In eastern England this enabled thousands of people from scores of communities to take part in community-instigated projects including local excavations which engaged communities while also advancing understanding of long-term change (Lewis 2016). The UK Localism Act (2011) introduced "Community Rights," which encouraged communities to draft "Neighbourhood Plans" to shape local development and nominate buildings or land (in private or public ownership), including heritage, as Assets of Community Value, which could not then be sold without the community being given exclusive first rights to bid for purchase. The gulf between community archaeology and the "professional" archaeological sector narrowed, in the United Kingdom at least, as loss of income from developer-funded archaeology in the post-2008 financial recession encouraged many professional archaeological organizations to offer their services to independently funded community archaeology projects.

At universities, engagement with local communities has been encouraged by burgeoning interest in coproduced research (devised and run jointly between universities and communities). Since 2014, papers in each issue of the new *Journal of Community Archaeology and Heritage* show community archaeology as routinely participative as well as consultative and instrumentalized.

The present

Over decades or, in some places, over centuries, the relationship between archaeology and communities has evolved, at different rates and not always happily, from one characterized by oblivious elitism and exploitation successively to embrace consultation, participation and instrumentalization and to nurture coproduction and community autonomy. The core aims and objectives of community archaeology are now well-established, its outcomes are increasingly widely valued, and its underpinning principles embedded in legislation and professional practice

in countries as far apart as Australia, Canada, and the United Kingdom as well as by the World Archaeological Congress and ICOMOS, while there are a growing number of forums in which experience, practices, and principles of community archaeology can be shared, sustaining a usefully informed and largely collegiate, outward-looking dynamism.

The future

In the future, community archaeology will need to develop its capacity to evidence its achievements and to refine understanding of the relationships between communities and archaeological remains and the mechanisms and processes which can articulate these for the common good (Gould 2016). There is scope to improve its ability to work in a truly interdisciplinary manner to achieve wider social aims, improving synergies with disciplines such as community work, social work, education, public health, and psychogeography to advance understanding of how communities work (Isherwood 2012). Community archaeology will need to increase its reach and diversity so that its benefits can be more widely felt by people, communities, and archaeology. It will need to respond to new digital technologies, which will not only diversify the ways in which wider publics can engage with archaeological investigation (already evident in crowdfunding, crowdsourcing, live streaming, gaming, and augmented reality) but also enable communities to form and act in new ways, including in how they relate to archaeology. Most importantly, community archaeology will need to respond to a changing world: the comments of Shelley Greer and colleagues writing in *World Archaeology* 15 years ago that “Archaeologists may expect increasing contestation between themselves as ‘experts,’ the community, and regulators until such time as new methods and practice are introduced which provide for adequate community involvement” (Greer et al. 2002, 283) are resonant in 2017 as populism and nationalism rejecting so-called “elites” and “experts” are loudly heard in political discourse.

Heritage and Conflict Resolution

CARSTEN PALUDAN-MÜLLER

NIKU, Norwegian Institute for Cultural Heritage,
Norway

Heritage is about inherited identity, a means of building and reaffirming cohesion within a group, and distinguishing it from others. Therefore, heritage is sensitive in conflict between groups; sometimes destroyed, sometimes looted, sometimes given or taken back. The Arch of Titus in Rome depicts the victors carrying away booty from the destruction of the temple in Jerusalem in 70 AD, an act that still resonates in today's regional conflict.

When heritage is returned after conflict it may happen as part of a unilateral process reasserting identity and rights, or as part of a reconciliation, recognizing the sovereign identity of "the other." Historically destruction is better documented than the use of heritage for conflict resolution. Cicero denounced the illegal appropriation of cultural property in 70 BC, but the restitution of war booty is first documented with the return to Italy by British troops of heritage from Louvre that had been looted by the Napoleonic armies. Third party postwar restitution remained the prevailing form also after World War II. Examples of voluntary direct restitution between former adversaries remain rare, but reconstruction of built heritage as a means of conflict resolution between former adversaries is sometimes seen.

Direct restitution has however emerged as a manifestation of postcolonial understanding of indigenous people's rights. Former colonizers (whether foreign states, e.g., United Kingdom or France, or states imposed by European colonizers, e.g., United States or Australia) have returned museum objects to the heirs of people whose rights were violated.

Types of conflict-impact on heritage

When heritage is destroyed during armed conflict it happens for a variety of reasons, working in combinations or alone:

Collateral damage is probably the most common cause for destruction. Fortifications for example were built in positions of strategic importance, and are therefore still likely to attract military activity. Today's warfare is increasingly urban, and historic urban structures will be affected. Buildings such as bridges, belfries, and minarets may become military targets.

Damage inflicted for economic reasons plays a major role. Historic structures may become seriously degraded when adapted for shelter by civilian refugees. Illegal and legal art markets can encourage looting, especially of archaeological sites. This trade already exists in peacetime, but tends to accelerate when war reduces other income for civilians and warriors.

Deliberate targeted destruction is designed to demoralize a population defined as enemy. By destroying people's historic imprint on a landscape, their historic right to presence is denied. Often it comes with ethnic cleansing, as seen during the 1990s Yugoslav wars, or in the aftermath of the 1915 Ottoman expulsion of Armenians from Anatolia.

Unintended destruction of built heritage may also follow ethnic cleansing. When buildings and monuments are abandoned by their original inhabitants, they may suffer from lack of use and maintenance or from an unsympathetic use.

Damage by disrespect arising from a perception of colonized cultures as inferior, for example the removal of antiquities or human remains to museums and universities in the colonizers' country, deprives people of their heritage, even if the aim was ostensibly to "preserve."

Using heritage for conflict resolution

The possibilities for using heritage as a means of conflict resolution depends on why and how

heritage in each instance was affected by the conflict, and on the conflict's current state: settled (i.e., the parties have accepted its outcome, such as World War II), or frozen (i.e., the *casus belli* or disagreements remain unresolved (e.g., Cyprus, Kashmir, Nagorno-Karabakh)). Whether the populations involved still live where they used to before the conflict is equally important, and so is the question of whether the former adversaries live as neighbours or are segregated. Finally, it matters under which political, social, and economic conditions the parties live.

The major challenge of working with heritage as a resource for conflict resolution is the plethora of parameters affecting the outcome. This is not a field where archaeological, architectural, or art historian expertise suffices. Depending on circumstances, different constellations of expertise from social sciences, psychology, economics, police, and military will be necessary for the success of a heritage project aiming at contributing to conflict resolution. Still more important is to involve the different fractions of the population.

Case studies

The following provides an overview with examples drawn from a variety of contexts of heritage used for conflict resolution.

Postcolonial conflict resolution deals with restoration of respect for the dignity of the colonized party. Europeans and North Americans legitimized their subduing of other people and their lands as a "*mission civilisatrice*." Colonization not only took place in the form of overseas expansion, but also as continental expansion into lands inhabited by indigenous populations that was not necessarily declared as colonization but presented as "natural expansion." This is how the United States (itself originally an overseas colony) expanded towards the west and south, Russia expanded east, north, and south, and Sweden and Norway northwards into Sami lands.

The study of colonized people and their cultures was part of colonialism's ideological project, and often involved moving artifacts and human remains to museums and research institutions for exhibition and study. In 1915 researchers from the University of Oslo removed 94 Sami

skeletons from a local burial ground in Neiden, northern Norway and brought them to Oslo (Svestad 2013) to study a population that under the prevailing race-theoretical paradigm was a primitive proto-Mongolian race. When the question of the ethics of holding on to the remains was eventually raised, a commission including representatives of the Sami authorities and the local community was established to seek a solution. The result was a reburial in 2011 near the original graveyard, but it was a decision accompanied by doubts and questions. The ritual for reburial was difficult to decide upon, since some skeletons were pre-Christian and others not. There were some voices in the Sami community in favour of keeping the collection as a unique material for research. The whole revisiting of the 1915 removal of the skeletons from the burial ground reopened old wounds in the local community. This is just one out of many global examples where indigenous people have reclaimed remains of their ancestors.

Post-Civil War conflict resolution is increasingly relevant with civil wars becoming a dominant form of armed conflict at this stage of history. When a fragile peace was finally established in Bosnia, the international community engaged heavily in projects to bring back damaged heritage. Often the focus was on the symbolic value of the monuments. The single most famous example is the restoration of the Mostar Bridge, feeding both on the phenomenological metaphor of "the bridge" and its well-published destruction by Croat forces. The project drew considerable global media attention and support from UNESCO, the World Bank and the EU. Yet it is debatable how well suited it is as a model for future projects.

Basically, there are three main lessons to learn from the Mostar project: First, physically the bridge did not span a gap between the Bosniak and the Croat part of Mostar. Both sides of the river were inhabited by Bosniaks. The bridge was a sixteenth-century Ottoman construction and by the Croats seen as "not our heritage." Secondly, the internationally funded project failed to meet this challenge by engaging the local Croat community as stakeholders. Finally, despite high publicity the reconstructed bridge together with other internationally funded restoration works was insufficient to help Mostar develop

an independent tourism that could generate significant income and employment for both communities. Mostar remained a subordinate destination for one-day tourists, generating little economic activity. It is easier to point to such shortcomings than to offer an obvious recipe for success, but there should have been stronger focus on working with the local communities of (former) enemies as key stakeholders, and on integrating the projects in a socioeconomic program that would benefit all sides.

Some of the Bosnian heritage projects are not contributions to reconciliation, rather they have created enhanced landmarks of entrenchment. Such is the case when churches are rebuilt with higher belfries than the originals, or when mosques are rebuilt not in the original Bosnian style, but in Wahhabi style reflecting the source of project funding instead of heritage.

Civil wars can be difficult to separate from wars between states. Cyprus is an example of a civil war that immediately accelerated into a Greek–Turkish war. After the war, the international community engaged in heritage projects on both sides of the Green Line, dividing Greek and Turkish controlled parts of the island. The projects in Nicosia/Lefkosia are focused on both Turkish plus Muslim and Greek plus Christian heritage conveying recognition of a duality of Cypriot heritage on both sides of the Green Line. But that duality may itself become over emphasized at the cost of the hybridity between Greek, Turkish, and Levantine culture that is an important constituent of Cypriot heritage.

Post-World War II reconciliation and conflict resolution with heritage as an asset has been exemplified with considerable variety. We can distinguish projects focused on reclaiming heritage destroyed during war, from projects focused on heritage generated by war (i.e., battlefields and memorials). In the first instance, we can think of the seventeenth century Frauenkirche in Dresden, which was one of many historic buildings (Neutzner, Hermann, and Zwicker 2006) destroyed during the British and American air raids on February 13, 1945. This example is particularly illuminating because the building and the story of its destruction has served different ideological narratives (see Rothenburg 2015, 98–127).

Firstly, in the last days of the Nazi regime it was used as an example of allied barbarism that

destroyed the historic city. Secondly for the GDR regime it served as an example of the inherent barbarism of the “Anglo-American air-gangsters” now the main enemy of the Soviet-bloc. During the cold war the ruin was left as a monument to the enemy’s cruelty. After unification of the two Germanys, a huge international fundraising operation was launched to rebuild the church as a monument for peace and reconciliation. Dresden was twinned with Coventry, a British city that had suffered an equally devastating German air raid. Today church and political leaders from both cities commemorate together on the anniversaries of the two bombings. On top of the dome of Frauenkirche sits a golden cross crafted by a goldsmith from Coventry whose father took part in the bombing of Dresden. It could have been a perfect example of heritage used for reconciliation. But the history of the bombing remains disputed. Every year accompanying the official commemorations there are violent confrontations involving both right and left. There are also minor manifestations to disrupt the official program and challenge the official narrative. Still the main emphasis of the commemoration is on dignity and reconciliation and on reaching out towards victims of present conflicts. The Frauenkirche had been destroyed in a way that can be perceived as an act of targeted heritage destruction and its reconstruction as an international initiative, and its consistent use as a focus for joint commemoration with Coventry, is an example of a heritage project that has contributed significantly to reconcile populations once seeing each other as enemies.

Post-World War I. The first industrialized armed conflict saw sufferings and destructions on a hitherto unseen scale. The war created heritage in the form of titanic destructive transformations of large landscapes. Places such as Verdun were transformed physically and mentally, in such a radical way that they reached a point of no return to what they had been before. The landscapes around Verdun became hallowed ground, a monument for the sacrifice of the French nation in an epic fight with Germany (see Amat, Filippucci, and Savouret 2015, 46–68). Six villages that had been at the centre of battle were never rebuilt, but left as monuments and declared, “*Mort pour la France.*” As time and generations passed, a

transformed nature matured and the memories of those who lived through the war gradually gave way to the reception of those who came after. Some of the most obvious scars of war became less manifestly present, and through several stages the perception of World War I evolved from one of national sacrifice to that of a seminal disaster in a common European history. When at the seventieth commemoration in 1984 French President Mitterrand and German Chancellor Kohl stood hand in hand at the monument and cemetery of Douaumont (Verdun), the understanding of common tragedy, suffering, and reconciliation was definitively given preeminence and included in a meta-narrative of European unity.

In recent decades, archaeology has made significant contributions to highlight the conditions of the soldiers who fought (Desfossés, Jaques, and Prilaux 2008; Schnizler and Landolt 2013). This helps penetrate the anonymity created by the massive scale of the armies and of the industrialized killing. Today at Verdun French and German flags fly together alongside that of the European Union.

Post-Holocaust

In another field of industrialized mass killing archaeology has proved its potential. The archaeology of the KZ-camps of the Third Reich has developed a strong contribution to the understanding of the extent of the camps and their individual roles in the system of mass extermination of people defined as enemies by Nazi Germany (Colls 2012). This exposure of physical evidence is crucial for the common ability to remember, to learn, and to avoid future conflicts escalating into similar crimes.

Characteristic of these examples of heritage from the two world wars is that both Dresden and Verdun have lately been explicitly used in an open discourse to reconcile former enemies. The acts of war have been openly dealt with in the process. There are other examples where conflict resolution and reconciliation is more difficult. In the relationships between Japan and the countries it attacked before and during World War II heritage has not been used in the same way. The many Koreans who died in Hiroshima were not part of the official motivation for Hiroshima's

World Heritage Status. The repeated visits by Japanese government members to the Yasukuni Shrine in Tokyo that commemorates persons who had served the nation and some of whom are also listed as war criminals by other countries is an example of heritage (the shrine) used in ways that prolong the themes of conflict.

Turkey–Armenia

Heritage projects serving reconciliation need not deal openly with difficult issues related to conflict. After 2010, there has been increasing cooperation between Turkish and Armenian experts in the preservation of Armenian heritage on the territory of the Turkish republic. The focus has been on strictly antiquarian issues related to surveying and ranking of the monuments and their need for preservation. Often, they are of very high historic value but heavily damaged, sometimes by nature sometimes by human action, with or without intention. The fact that the Turkish authorities in 2012 nominated the historic city of Ani for UNESCO World Heritage status (granted 2016) has been an important gesture towards the Armenians. Even though the two parties seem unable to establish a common understanding of what happened to the Ottoman–Armenian population in 1915, they can now use heritage as a platform for cooperation and dialogue.

Conclusion

The development of projects using heritage for reconciliation should understand the factors behind the conflict in the first instance, and what role identity and cultural heritage have in the conflict. Social and economic factors such as unemployment and poverty may be the most important drivers behind a conflict, whereas identity as expressed through religion, language, and heritage may offer markers of difference, instrumentalized as symbolic rallying points for the parties to escalate the conflict. Heritage projects aiming at conflict resolution should address both the socioeconomic and the symbolic aspect. This can be done by using heritage to generate jobs and income (Lindblom and Paludan-Müller 2012) and through an emphasis

on heritage as an expression of exchange of impulses from various cultures. In areas of mixed cultures where communities have been pitched against each other, it is crucial to emphasize hybridity and common heritage.

Heritage and Ecomuseums

PETER DAVIS

Newcastle University, UK

The most recent definition of an ecomuseum is “a community-based museum or heritage project that supports sustainable development” (Davis 2011, 85). At the core of ecomuseums lie the key elements of community, place, and characteristics that include holism, territoriality, democracy, and an inclusive definition of heritage (nature, culture, intangibles). Ecomuseums are often defined by a geographical territory, but one that might cut across political boundaries, or be defined by a shared past, or by a patois or a tradition.

No matter where they are located in the world, all ecomuseums are deeply embedded within a locality and reflect and celebrate local identity and local distinctiveness. Community dialogue, debate, and participation are central to ecomuseum principles; these processes deliver more meaningful interpretations of how local heritage—including archaeological sites, the built environment, local traditions, and the natural environment—reflects aspects of place. It includes the histories of inhabitants and all the sources of evidence, tangible and intangible, that have been socially identified and constructed to be considered of lasting value. However, ecomuseum practices are not simply dedicated to conserving aspects of heritage, but also provide a system of norms and values that contribute to shape habitus and a locality where “sense of place” is manifest. Ecomuseum establishment enables communities to identify, conserve, interpret, and manage their natural and cultural heritage resources for sustainable development—communities recognize and conserve heritage for themselves, which represents a “bottom-up” approach which runs counter to the “authorized heritage discourse” (Smith 2006).

The idea of the ecomuseum is perhaps best demonstrated by an example. The Ceumannan

Ecomuseum is based in Staffin, the most northerly peninsula of the Isle of Skye, Scotland, arguably one of the most spectacular landscapes in Britain. The area is one of rugged mountain scenery hiding secluded grassy plateaus and small freshwater lakes, and has a dramatic coastline with stacks, pinnacles, and hidden coves. The coastal rocks are predominantly Jurassic age with Tertiary exposures, rich in fossils and supporting colonies of breeding seabirds and populations of rare plants. In 2004, the Staffin Community Trust was awarded almost £200,000 from the United Kingdom's Heritage Lottery Fund and European sources to develop an ecomuseum, the first in Scotland, and indeed the first in the United Kingdom at that time. The Trust, which includes representatives from local voluntary groups and organizations, took responsibility for development, with aims to stimulate economic growth through tourism, encourage social activities in the community, improve local services, and strengthen sense of place. Ecomuseum supporters have undertaken a range of ambitious projects. Aware of the wide range of natural and cultural assets that attract geologists, naturalists, and walkers, projects have been largely devoted to historical and environmental themes.

The Staffin Ecomuseum promotes 13 sites of interest to visitors and local people by encouraging them to discover the area on waymarked trails. These include Quiraing, the rock face that towers above Staffin; dinosaur footprints on the shore at An Corran; Flodigarry's Viking connections; scattered crofts at Brodaig; and the Staffin Museum at Ellishadder which houses excellent local geological collections. This low-key ecomuseum could be a model for many others to follow; it is closely linked to community identity, local history, memory, sense of place, and economic development.

The roots of the ecomuseum movement can be traced back to France in the 1960s, although the word “*écomusée*” only came into use in 1971 after being coined by museologist Hugues de Varine. Since then the concept of the ecomuseum has evolved from its initial focus on rural material culture and lifeways, becoming adopted as a

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0277

means of achieving community-heritage projects within a defined geographical territory in order to benefit local communities and conserve heritage assets. Early ecomuseum definitions included that of Rivard (1988, 125) who provided a useful comparison between the traditional museum (building + collections + experts + public) and the ecomuseum (territory + heritage + memory + population), whereas Varine suggested that the label ecomuseum was nothing more than “an opportunity to run with new ideas, to be imaginative, to initiate new ways of working, even to be audacious” (de Varine 1992, quoted in Davis 2011, 83). Today, the concept of the ecomuseum is regarded as an active expression of the school of thought known as “New Museology” that emerged between the 1960s and 1970s; the original new museology focused on how museums might assist disadvantaged communities, becoming a social actor in a process of societal, cultural, and environmental transformation. While traditional museums have frequently favoured high culture, ecomuseums encouraged an appreciation of the significance of “commonplace heritage” as local people began to recognize, value, and interpret their own cultural and environmental resources. This approach chimes nicely with the philosophies of the United Kingdom-based organization Common Ground, which has done much to generate enthusiasm for “everyday” heritage.

More than 400 ecomuseums exist around the world, the majority in Europe. They demonstrate huge variety in terms of the extent of their geographical area, from the Kalyna Ecomuseum in Canada which covers several thousand square kilometers of Alberta (and includes a National Park as well as other wilderness areas) to the Hemp Ecomuseum in Carmagnola, Italy, an old rope works which is housed in a small outdoor space of a few square meters. The ecomuseum observatory database (www.irespiemonte.it/ecomusei/) records that 98 percent of ecomuseums are located in rural areas and emphasize the link with local history, archaeology, local landscapes, natural resources, biotopes, and agricultural practices.

Ecomuseums also differ in terms of their management and governance practices. Although ecomuseum philosophy suggests they should be initiated and managed by local communities, a significant number are privately managed

or have been created by public bodies such as National Park authorities or local government to create networks of local heritage attractions, many of which are volunteer-led. However, the majority of sites are managed by, or work closely with “Associations,” local interest groups of activists. Ecomuseums jointly managed by local associations and public authorities are also common. For example, the Ecomuseo del Castillo de Ainsa (Spain) is a rural ecomuseum managed by the Fundació por la Conservación del Quebrantahuesos, a national nongovernmental organization which has the objective of assisting the recovery of populations of the Bearded vulture (*Gypaetus barbatus*) in the Spanish mountains. The Babia Góra Ecomuseum in Malopolskie, Poland is an ecomuseum founded in 2003 and managed by a local association; it promotes a network of places of natural and cultural heritage interest. The Ecomusée Daviaud in the Vendée region of France is an active member of the eco-Vendée network managed jointly by the local communes of Ocean-Marais de Monts.

Theoretical discourse about ecomuseums frequently makes connections to concepts of place and “sense of place.” Feelings about place may be derived from the natural environment, but are more often made up of a cocktail of natural and cultural features, and include the communities that live there. Our perceptions of places affect us, and places modify our behavior. In terms of heritage, this is important when we try to understand its significance and the role that heritage might actually play in the construction of “sense of place.”

All people have their own place, or perhaps several places, where they feel they “belong.” Terms such as “belonging,” “sense of place,” “identity,” and “community” are all related to ideas about place. Other terms seeking to capture the relationship between people and place, including sense of experience, topophilia, place identity, place attachment, insidedness, local sentiment, and community sentiment, have been coined by academics from several disciplines, including psychology, geography, anthropology, ecology, sociology, and cultural and heritage studies. These views, which stress attachment to place, have led Davis (2011) to claim that a major objective of ecomuseums is to strengthen sense of place and to promote a positive and

dynamic relationship between communities and their environment. Unsurprisingly, the “alternative heritage discourse” regards local people as the guardians of their own place and their own heritage, and the key actors in preserving the distinctive characteristics of their place (Smith 2006). This emphasis on local heritage and territorial identity—and the role of inhabitants in the regeneration of places—can be regarded as a reaction to globalization and cultural homogenization. Community engagement is increasingly recognized in UNESCO Conventions, and in the European Landscape Convention guidelines, which emphasize the interrelationships between local people and their environment.

Casey (1996) argues that place must be experienced: “there is no knowing or sensing a place except by being in that place, and to be in a place is to be in a position to perceive it;” in other words, place becomes a conceptualization of identity. Hence, ecomuseums are important in

that they provide a means of place exploration and help to express a deep conviction to preserve and deepen their own sense of place. They have the potential to provide local people with a process for rescuing fragments of heritage, a building, a redundant factory, a habitat, a form of intangible heritage, or a way of life from loss or destruction. To aid place exploration, many ecomuseums have developed a “fragmented site” approach, encouraging the visitor to explore the local area by visiting several local heritage sites. This split-site approach is arguably the most common feature of ecomuseums worldwide; the ecomuseum is not limited to a building or even a museum site, but encompasses everything within the region it refers to as its “territory.” Here, key sites have special meaning and are integrated into the museum. Heritage is recognized as being more than just archaeological or historic sites and material culture: it also encompasses memories, beliefs, folklore, legends, dance, music, and

Figure 1 The necklace model for the ecomuseum.

song. At the extreme, the ecomuseum includes everything within its territory. Intangible local skills, behavior patterns, social structure, and traditions are as much a part of the ecomuseum as the tangible evidence of landscapes, archaeological remains, geology, wildlife, buildings, and objects, and people and their domestic animals. Ecomuseums can be conceptualized as the string of a necklace holding together these heritage assets (Figure 1) (Davis 2011).

In conclusion, it is important to recognize that ecomuseums, local heritage, and places are deeply connected; the one characteristic that appears to be common to all ecomuseums is their pride in the place that they represent, promoting both its natural heritage and tangible and intangible cultural assets. Ecomuseums enable local people to gain social and cultural capital through their involvement; most importantly, they encourage dialogue between local people and visitors, so promoting a better understanding of the special nature of a locality, its history, sense of place, and local identity. Since the 2000s, ecomuseums have undergone a significant change in emphasis as their paradigm has been adopted to encourage economic growth, tourism, and gains in cultural capital. The new role for ecomuseums identified in China, to aid indigenous rural communities and safeguard their cultural assets (Davis 2011, 236), suggests that ecomuseums will continue to evolve to meet a wide variety of local needs as the concept becomes better known.

Heritage and Economics

JAN ROUWENDAL

Vrije Universiteit Amsterdam, Netherlands

Economics has been defined as the study of the allocation of scarce resources, where scarce means that the available amount is low relative to demand. Heritage, for instance, ancient inner cities or older housing with characteristic architecture, is appreciated by many, but in limited supply. How can the economic returns of this historic capital—the benefits it provides to visitors and inhabitants—be measured? Should investments in heritage be stimulated through the use of public money?

An important part of economics is the “theory of value.” Its purpose is the determination of the value to society of commodities and their efficient use. The market is the primary mechanism for the allocation of resources, but economists have also been interested in the valuation of goods that are not traded. The nonstandard properties of such goods make them more challenging to study. Heritage is a case in point. The remnants of the past that are still with us can hamper further development, but can also occupy a useful place in the present. Many European towns have inner cities dating to the middle ages, whose streets are obviously less fitted to automobiles and public transport. The restructuring of Paris from the 1850s directed by Hausmann destroyed substantial amounts of heritage but made the city more suitable for modern times. On the other hand, cities like Venice that preserved their built environment are generally considered to be an important part of society and to be highly valued.

Hausman’s Paris is today appreciated by many, but he encountered fierce opposition in his time. It was not clear to all that the loss of an earlier version of the city was outweighed by the creation of the new one perhaps better suited to modern needs. Economists tend to think of projects like this in terms of what they call cost–benefit analysis. They make a list of all the losses and gains

for society associated with a project and try to make them comparable by expressing them in monetary terms. If adding all entries results in a positive number, it is concluded that carrying out the project is in the interest of society.

The focus of this discussion is on applying this methodology to the built heritage, and more specifically on measuring benefits, because while the costs of maintaining heritage are often all too clear, the benefits are usually more difficult to measure. At this point economics, and more specifically the theory of value, can make a contribution.

Heritage often takes the form of an amenity that is available to many without any obligation to pay for it. Any visitor of Amsterdam can enjoy the canal belt without being charged. The absence of a price for this type of heritage complicates determination of its value. Economists have accepted the challenge and developed techniques to measure the value of such local public goods and in what follows, the application of some of them to value heritage will be discussed.

From a welfare economic point of view the valuation techniques just discussed are interpreted as revealing the social value of heritage, that is, the value that society attaches to this amenity. If one accepts the assumptions underlying this view—the most important probably being that it’s the *use* of heritage made by current and future generations that matters—the results of the valuation exercises have normative value.

Heritage indicators

Economists are not experts in heritage. They use quantitative methods to do their research, which often implies that they use crude indicators for heritage content like a 0–1 variable indicating the monument status of a property or the size of a preservation area expressed in square kilometers. This does not indicate a lack of respect for the many relevant aspects of heritage that cannot all be measured in a quantitative way, but should be interpreted as an attempt to make the best use of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0278

limited quantitative indicators. It is nevertheless the case that by using them, economic analysis runs the risk of missing relevant and interesting aspects of heritage valuation. Future work may address some of these shortcomings (Ahlfeldt and Holman 2015).

Property prices

Hedonic price analysis is probably the most important technique for valuing local public goods. It assumes that characteristics of a house jointly determine its value for the user. In a competitive market all aspects of this value will be reflected in the price. Potential buyers searching for a house compare their characteristics and prices, and look for the best choice. Think about two houses that are identical in all aspects, except one, for instance, heritage content. The difference in price between the two is the value consumers attach to this aspect. Even if such ideal pairs do not occur in practice, statistical techniques allow an estimation of the impact of one characteristic on the price. This technique provides information about the value of heritage embodied in the house itself. It can also be applied to assess the impact of heritage resources located in the vicinity.

Using monument status as an indicator of the heritage embodied in the house, it has been found that in Dutch cities heritage is worth 5–10 percent of the value of the house. Monuments in the vicinity have a much smaller impact that is only significant when there are many, as happens in ancient inner cities. Research has concentrated on houses, but there is some evidence that the same phenomenon is present for particular types of office activity such as notaries or some consultants, who are willing to pay a premium for being able to use historic buildings.

Monument status is a rough heritage indicator, covering a lot of heterogeneity. Its main advantage is that it is based on expert judgment. A potential disadvantage is that monument status often also implies that ownership rights are limited by obligations to preserve the monument, and in principle such restrictions may reduce the property's price. The premium for monuments measured by hedonic analysis should thus be viewed as the net effect of the average value that

the heritage resource embodied in the property has for its users and the effect of the binding restrictions implied by the monument status. More detailed investigations of the value attached to a heritage resource could be obtained by using more specific indicators. In practice they appear hard to find and the year (or period) of construction is often the only alternative for monument status. In the Netherlands houses constructed in the first half of the twentieth century are in strong demand. Hedonic price studies show that such houses do not depreciate but rather increase in value over time, in sharp contrast with houses constructed after World War II. Part of this increase may be caused by improvements introduced in such housing, but note that such investments are themselves triggered by the attractiveness of this vintage housing.

Urban areas

The research findings discussed in the previous section refer mainly to private benefits for the occupier of a house or office. The external effects of heritage, that is, the value attached to it by those who don't have to pay for it, are more interesting for social cost–benefit analysis. Many Europeans appreciate the amenities of older inner cities by regularly visiting them for shopping, dining, or entertainment while living in suburbs with modern housing. The inner cities are an amenity that is valued by the inhabitants of the whole urban or metropolitan area. One may attempt to measure its importance by studying the location choices of households. A recent literature in economics has emphasized that, next to jobs, consumer amenities also play a non-negligible role in making a city an attractive place. For instance, the contrast between central Paris and downtown Detroit probably has to do with the overwhelming amount of heritage present in the former city, including that created by Hausmann's transformations. This attracts richer households whose spending stimulates the presence of restaurants, bars, specialty shops, theatres, and so forth that further enhance the attractiveness of the central area. The vibrant city center is an amenity for inhabitants of the whole agglomeration and increases its attractiveness as a

place to live. In this way consumer amenities can act as an important complement to employment.

The study of household location assumes that households make a deliberate choice between urban areas based on their characteristics. The methodology is thus similar to that of hedonic analysis, although the focus of interest is now on the location and not on the price. However, if house prices adjust to the forces of demand and supply, they are explained as well by the location choice model. One can compute the willingness-to-pay of households for the various urban amenities. Empirical estimates indicate that this can amount to several thousands of euros (van Duijn and Rouwendal 2013). To interpret this number properly, it should be noted that it does not refer to the old buildings in the protected inner city *per se*, but to the ancient inner city as it functions in the current urban setting. That is, it is not just the medieval houses but also shops, restaurants, and bars that drive the results. The models do not allow the separation of the “bricks and mortar” of ancient buildings from their current uses. However, these endogenous amenities are themselves, at least in part, only there because of a heritage resource. Even after correcting for this possible overshooting, location studies suggest an enormous social value of urban heritage.

A particular advantage of studies of location choice, in comparison to hedonic analysis, is that they allow investigation of possible difference in the willingness to pay for heritage between household types. A general finding is that willingness to pay for heritage among higher educated people exceeds that of others (and only partly because of higher incomes). This is significant in view of the consensus among urban economists that a skilled labor force is of utmost importance for urban growth and prosperity. There is also some evidence that the attractiveness of urban heritage is stronger for those working in “creative” sectors, and weaker for those with “technical” jobs, like IT.

To conclude, a word of warning. The results just discussed should not be interpreted as denying that jobs have priority over amenities for making cities attractive. Household location studies show that heritage is valued less in areas without a strong concentration of jobs.

Tourism

The benefits of heritage extend even to people who do not live in the urban area in which they are located. Tourist spending is important for the local economies of many historic cities and is often its main industry. However, it would not be correct to regard all this expenditure as expressing the value attached to heritage. The reason is that most of these tourists would have spent their money anyway, although probably at different places. Put differently, heritage influences the distribution of expenditure but these are not welfare effects. To properly measure welfare effects, one should compare the actual situation in which heritage is present with an alternative one in which it is absent. Consumers would probably spend the same amount of money, but their utility would be lower. The total expenditure associated with their trips does not measure the willingness to pay for the specific destination.

The economist Harold Hotelling developed a methodology for measuring the willingness to pay for goods like national parks in the United States that laid the foundation for the modern approach for measuring the benefits of trip destinations. He reasoned that the travel costs associated with visiting a national park could be included as part of willingness to pay calculations. The “travel cost method,” as it became known, has later been generalized to situations in which consumers can choose from many destinations. Estimated models of trip choice behavior allow computation of the willingness to pay for additional heritage—for instance, more monuments or a larger preserved historic area. Such models have recently been estimated for vacations, shopping and dining trips, and trips to rural destinations with walking or cycling as the main travel purpose. In all cases heritage turned out to be a significant element of destination choice behavior.

Effects of investing in heritage

All the results referred to above concern the value of existing heritage. For policy makers the relevant question is often whether it is economically worthwhile to invest in heritage through

maintenance or restoration. Economists attempt to answer this question from a welfare economic point of view. Subsidies to maintenance and restoration are justified if the social benefits exceed the cost. If all the benefits of such activities accrue to the owner of the property, there is no reason for spending public money on them. However, if there are benefits to others who do not pay for it—the inhabitants of the neighborhood in which the property is located being potentially the most relevant group—the owner does not have the proper incentive to take the right decision. If they have to bear the full cost while gaining only part of the benefits, they will be inclined to underinvest in maintenance and restoration. A subsidy equal to the benefits that will be experienced by the others is then justified, but to determine the value of this subsidy these external benefits have to be estimated.

Recent research has employed hedonic price analysis to address this issue. The idea is that investment in heritage—subsidized restorations of national monuments—has an impact on the prices of nearby houses. The area becomes more attractive as a residential location, hence demand increases and (with limits on the supply of new housing) therefore house prices rise. The higher prices reflect the value attached to the improvements in the national monument and can therefore be interpreted as the willingness to pay for it by the residents. As an example, spending 1 million euros on restoring a national monument in the Netherlands leads to an increase in house prices in the vicinity of approximately 3 percent (Koster and Rouwendal 2017). Although this may not appear to be a large number, the relevant area is large enough to make the total external benefits exceed the cost.

Another recent study investigated the redevelopment of abandoned manufacturing sites in the Netherlands that were kept in large part in their original state. It was found that the negative impact on the surrounding neighborhood that was present before redevelopment disappeared, and could be replaced by a positive external effect. This happens mainly in urban areas, however, and is hardly measurable outside the larger cities. It is not entirely clear what causes this difference, but perhaps rural open landscapes provide a good substitute for living in the vicinity of

manufacturing heritage (van Duijn, Rouwendal, and Boersema 2016).

Heritage in the urban landscape

Heritage is often part of urban areas and codevelops with the cities in which it is located. Although the literature on which the previous sections were based takes the designation of monuments and preservation areas as exogenous, this is in reality almost certainly not the case. Designation is only useful if there is a commitment from residents and local authorities, and the experts that decide on designation often take this into account. The presence of well-educated residents with higher incomes helps to stimulate interest in the preservation of characteristic buildings and to support joint efforts to preserve the characteristics of a neighborhood. Designation as a preservation area strengthens this process by ensuring continuation of that practice and thus offers some protection to the required investments (Ahlfeldt et al. 2017).

Protected status implies restrictions on future (re)development which bite more if the option to redevelop in an unrestricted way is more binding. Consistent with this observation, it has been found that protected areas on Manhattan, the most dynamic part of New York, did not show higher prices than surrounding areas, whereas properties in protected areas in other parts of the city were significantly more expensive (Been et al. 2016).

Recent developments in the literature paint a more vivid picture of the role of heritage and the way we deal with it in urban and regional economics. The economic importance of heritage is established beyond reasonable doubt. Current and future research may be expected to clarify further the processes that lead some buildings to end in obsolescence and demolition, while others are—often also after a troublesome period—rejuvenated and successfully integrated into a significantly changed environment.

Heritage and Human Rights

TIM WILLIAMS

University College London, UK

The universal nature of human rights was set out as *for everyone without distinction* in the Universal Declaration of Human Rights (UDHR), which was adopted by the United Nations General Assembly on December 10, 1948. However, the definition of human rights, as set out in the UDHR and subsequently in international law, does not define the role of culture or of cultural rights. UNESCO (1970) debated whether human rights included cultural rights—such as the right to participate in cultural life, the place of culture and tradition, group rights versus individual rights—and argued that these should be given attention. Over the past few decades, a number of meetings, conventions, and publications have debated the issue of cultural rights (Silverman and Ruggles 2007; Langfield, Logan, and Craith 2010; Meskell 2010; Ekern et al. 2014). However, these debates also concluded that the right to culture is limited at the point where it infringes on another human right. We can thus argue that cultural rights cannot simply be placed on a par with human rights, not least because “some cultural rights as locally practiced might be argued to abrogate human rights” (Silverman 2014, 7875). Similarly, “human rights and cultural heritage are not self-contained; they may overlap and in doing so may conflict with each other” (Silverman and Ruggles 2007, 6). This clearly sets up a tension as to whether culture, or specifically heritage, is a fundamental human right.

Unsurprisingly, there is no clear definition of cultural rights or agreement on their status, in part because cultural values are always contextual not universal. Heritage is contextual because it lies in the interplay between values—not simply local and nonlocal values, but also values among and between individuals and groups. These may be in conflict and are seldom shared—certainly

not on a universal scale. Nevertheless, there are certain strengths to considering cultural rights. As Appadurai states:

the global commitment to cultural heritage can be given a new relevance by using the perspective of cultural aspiration. This has a double value since cultural heritage can include problematic memories, divisive values and anti-democratic practices. By insisting on a constant dialogue between the capacity to aspire and the capacity to remember, we can provide a system of checks and balances, so that aspirations do not become unrealistic and memories do not become exclusive or xenophobic. (Appadurai 2002, 11)

Human rights such as dignity and justice surely need to be seen as driving forces behind decision making with regard to heritage and its management. The issue is about power in decision making—not about cultural rights per se. Many argue that the language of international human rights has shifted toward a unified language of global justice and governance. “Rights talk thus operates to leverage power in arenas of political debate and discourse ... using the language of rights can underscore the importance of the interests at stake, and the need for special kinds of justification attached to those interests” (Meskell 2010, 853). It is this rhetoric that may prove most useful.

A workshop in Oslo in 2011 entitled “Our Common Dignity: Towards Rights-Based World Heritage Management” (papers were published in the *International Journal of Heritage Studies*, and then as Ekern et al. 2014) advocated a rights-based approach to heritage management as a means of centering such debates. Subsequently this concept has been expanded upon in a joint IUCN, ICOMOS and ICCROM report from a workshop entitled “Building Capacity to Support Rights-Based Approaches in the World Heritage Convention: Learning From Practice” and held in Oslo in April 2014 (see IUCN, ICOMOS, and ICCROM 2014). This development may offer an important way forward in conceptualizing an ethical standpoint for heritage management.

Values: the intersection of cultural diversity, heritage, and human rights

It is evident to anyone who works in the field that there are problematic disjunctures between conserving and managing cultural heritage, recognizing diverse values and stakeholders, making heritage intellectually accessible, maintaining and promoting cultural diversity, and developing participatory processes, when all of this is set against a broader and fundamental backdrop of supporting and promulgating human rights.

Values-based management has received considerable attention in recent years, providing a theoretical conceptualization of the importance of recognizing, articulating, and taking account of differing views of the same realities, of different ideas of importance to heritage—places, landscapes, and materialities—and their associative values, and of different perceptions of the importance of heritage for the present and the future.

UNESCO, in its cultural conventions, has emphasized the understanding of and tolerance for other cultures and has founded concepts that are based on universal values and mutual respect across cultural boundaries. But what are universal values? How does this notion accord with local values and with the spatially specific and contested nature of heritage?

The definition of an outstanding universal value (OUV), as expressed in the most recent version of UNESCO's Operational Guidelines at the time of this writing—the 2016 one—is as follows: "Outstanding Universal Value means cultural and/or natural significance which is so exceptional as to transcend national boundaries and to be of common importance for present and future generations of all humanity" (para 49). However,

a major challenge with World Heritage concerns a risk of gradual disassociation of OUV attributes from the values of local communities, social practices and lives. First, local values, cultural continuity and practices have often been dismissed by international conservation priorities. Second, an often held misperception is that effective protection of OUV requires excluding or displacing local values and their holders. (IUCN, ICOMOS, and ICCROM 2014, 7)

Indeed, there would appear to be a basic and fundamental contradiction between UNESCO's emphasis on diversity and the concept of universal value.

As Helaine Silverman (2014, 7875) asked: "Can and should cultural rights and human rights be universalized as encompassed by UNESCO's various declarations—beyond the idealistic notion of all of humankind being enriched by the enjoyment of everyone's cultural heritage?" When identifying "universal values," UNESCO is effectively putting forward a simplified version of historical value or significance, as perceived by a subset of heritage professionals. Key values of economic development, identity (local or national), political recognition, and so on are not overtly part of the selection criteria: but we are well aware that these are among the key values that drive state parties to nominate properties, and are very often part of the crucial political context for the World Heritage Committee's decision-making process. These values also lie at the core of many of the conflicts between the state and local stakeholders, and often at the core of development issues that directly impact upon the human rights of local communities. These conflicts create tensions between the values of international communities, states, and local communities; between professionals, bureaucrats, administrators, experts, and users; between local knowledge and professional expertise.

Heritage is often seen as vital for the articulation of cultural identity. So where does that leave the local, the state, and the international community when it comes to reconciling different values? Lynn Meskell (among others) has argued that, "in an ideal world, 'heritage rights' would include rights of self-determination and expression, rights of access and management, rights of veto, and rights to accrued benefits whether social, economic, spiritual, and so on" (Meskell 2010, 842). These ideas are echoed in many works that advocate a "living heritage" approach.

However, a distinction might be drawn between contemporary communities engaged the use or conceptualization of heritage spaces or places, or in material culture (such as indigenous communities), and contemporary communities that inhabit the space previously occupied by past societies with whom they may or may not feel any relationship and in whom they may or may

not be interested. Indeed, most contemporary societies have witnessed historical or ongoing migration, which profoundly changes the way people perceive their societies, and also impacts their engagement with the past societies that lived in the place they now inhabit. In all these cases heritage may be more or less important in framing an understanding and appreciation of “place” for local people; but it also recognizes that its own value will be different for different people and groups. Heritage also recognizes that this may well extend beyond local inhabitants. Tourism, heritage, and cultural organizations have all used the concept of “unique” to promote cultural tourism, to define a competitive advantage over other destinations. But this “uniqueness” is also used to define a place, a community, or even a state, which can lead to conflict over values and identities and can bring cultural values directly into conflict with human rights.

Recent debates, keen to be seen to be moving away ethically from top-down solutions and from the dominance of “expert opinion,” risk creating similarly simplistic and naive positions, which favor the rights of local inhabitants over those of all others. Expertise is not easily acquired in any field, and to disregard experts in heritage management, conservation, archaeology, education, tourism, and so on would be as disastrous as ignoring local values. The idea of a veto, or predetermined rights of accrual, on the basis of proximity to a heritage site, needs to be treated with caution. It also follows that the concept that “heritage rights, by their very nature, are likely to be locally and culturally understood” (Meskell 2010, 842–3) is an oversimplification: many values will be best understood at this level, but not all, and the notion of wider value judgments, of examining from different perspectives, must not be underrated or sidelined.

There is, however, no doubt that heritage and, specifically, heritage sites have been used as powerful tools in both supporting and attacking the human rights of communities throughout the world. The display and the interpretation of heritage sites have been used to assert minority identity—as a tool for resistance and the expression of difference—and, conversely, to oversimplify cultural differences and to assert alternative nationhoods. The latter, in particular, have challenged political autonomies and undermined

the values of communities, destroying the “very fabric of society” (Silverman and Ruggles 2007).

Therefore it is important that many archaeologists and heritage professionals increasingly see themselves as conduits and facilitators rather than arbiters and seek to enable all stakeholders and affected communities to engage in the decision-making process and in its outcomes. It recognizes the different rights of stakeholders to be part of the decision-making process, not simply part of a consultative paradigm. This move from values-based management to rights-based management may herald a more ethically centered discipline, which recognizes the role that heritage management and heritage rights have to play in supporting broader human rights.

Conclusion

We need to be very careful that cultural rights are not simply equated with more fundamental human rights, as set out in the UDHR. Article 2 of the 2005 UNESCO Convention on the Protection and Promotion of the Diversity of Cultural Expressions stated (visit http://portal.unesco.org/en/ev.php-URL_ID=31038&URL_DO=DO_TOPIC&URL_SECTION=201.html):

Cultural diversity can be protected and promoted only if human rights and fundamental freedoms, such as freedom of expression, information and communication, as well as the ability of individuals to choose cultural expressions, are guaranteed. No one may invoke the provisions of this Convention in order to infringe human rights and fundamental freedoms as enshrined in the Universal Declaration of Human Rights or guaranteed by international law, or to limit the scope thereof.

Nevertheless, we might argue that rights-based approaches are an extension of values-based approaches, in that they reflect the idea that some values are rights, not just interests or concerns. This could be a very useful construct, designed to promote critical debate on the values of specific heritage and the uses that it is put to. It could also ensure that the consequences of the decision making and actions of heritage professionals are considered within a broader framework than that of “what is best for the heritage.” Heritage is about

people and human values. Archaeologists and heritage experts are involved in the political ramifications of how heritage is used and perceived in the present. Exploring past societies, managing their physical remains, and interpreting these materials are twenty-first-century activities rooted in contemporary society and its issues: identity, political power, access to economic resources, development strategies, and so on can all be affected by what archaeologists say about the past. What is clear is that both the study of heritage and its preservation and management have to be set within wider concerns for human dignity and human justice. Practitioners do not need to be “deeply concerned about social, economic, and political inequities worldwide” (Silverman 2014, 7874) in order to recognize that, in contemporary society, their research and actions have consequences.

Understanding and empathy with plurality and cultural diversity, in recognition of the 2001 UNESCO Declaration on Cultural Diversity, must be critical to our thinking and teaching. As Andrew Sneddon (2014, 1895) comments, “the process of bringing the poor from the periphery to (or closer to) the center of heritage management has been a complex one.” The UN placed “lifting the world out of poverty” at the core of all its activities, and this is reiterated in its Millennium Development Goals. The UN’s cultural arm, UNESCO, stated that “key areas where culture can play a decisive role in the forthcoming international development agenda have been identified: poverty eradication, quality education, sustainable environmental management, sustainable cities, and social cohesion and inclusion” (see <http://en.unesco.org/themes/culture-sustainable-development>).

On the other hand, whether owing to external pressures, regional variation, or existing heritage practices, many world heritage tools and approaches remain grounded in expert knowledge and top-down planning. There is a continuous and urgent need to engage more actively with the implementation of rights-based approaches in the heritage sector (IUCN, ICOMOS, and ICCROM 2014, 8).

We need to see aspirational action. The Oslo workshop in 2014 suggested some useful policies, advocating that “governance following rights-based approaches is inclusionary and

shared, based on equality, adequate representation and mutual understanding” (IUCN, ICOMOS, and ICCROM 2014, 10). However, these policies continue to mix and confuse rights with democracy and rights with “being local” and fail to acknowledge that some cultural rights will be in conflict with other stakeholders’ rights or beliefs, or indeed even with their basic human rights.

Heritage and Landscapes

SJOERD J. KLUIVING

Vrije Universiteit Amsterdam, Netherlands

Landscape is experienced and conceived of in many different ways. In its broadest sense, landscape may be defined as a cultural or mental construct, a terrain adapted, constructed, or modified by people, or a direct result of natural processes. This entry focuses on the third and last definition, while keeping the other meanings in mind; and it focusses on European examples.

“Landscape includes everything, natural and human, that makes an area distinctive: geology, landform, soil, plants, wildlife, and patterns of human land use. It can be viewed in different ways, depending on the different natural and cultural values of the observer” (Stace and Larwood 2006, 11). Indeed, landscape has been given a variety of meanings and definitions and can be quite different for diverse observers or academic disciplines. Geologists, archaeologists, and historians each use different scientific definitions and descriptions, while landscape users have their own interpretation, which is dependent on the observation of their own environment. European city dwellers observe a colorful and variable landscape more or less unconsciously, as part of everyday life, but underneath the layers of urban building, agricultural fields, and infrastructural patterns a whole world of geological variability and natural diversity is present of which most people have no knowledge.

This is partly because Europe’s inhabitants have been disconnected from the natural world for more than a century (and even for longer in some countries), as a result of the fact that the Industrial Revolution dramatically changed the landscape (Fuchs et al. 2015). In daily life, people have very little awareness of the sometimes spectacular processes and remarkable shapes that underline landscape and are contained in the ground below their feet. All places on earth, however, have an identity that is grounded in

the rich heritage of landscapes, rocks, fossils, and mineral sites. To enrich society and to communicate the power of breathtaking and magnificent natural phenomena, it is necessary to (1) highlight the rich invisible geoheritage that is often linked with biodiversity and cultural heritage, (2) bring across the different meanings of the phenomenon called “landscape” both to landscape professionals and to the general audience, and (3) add landscape as heritage to the list of items to take care of in a sustainable world that will be resilient to future environmental and societal changes.

The task of making people aware of the landscape around them is an important one. With deeper knowledge and understanding, people will act more positively for a sustainable future for our planet, being aware of the natural diversity and beauty around them, realizing the long-term formation and development of their landscapes, answering to a sense of pride of their region, and thus accepting landscape as heritage. This entry offers three examples from the Netherlands and part of Belgium in northwest Europe. They come from mono-, inter-, and transdisciplinary perspectives and all three treat landscape as heritage.

Case study 1: The disguised beauty of the landscape of the Netherlands and the North Sea: a monodisciplinary approach

The landscapes in the northwest European lowland represent a diverse assemblage of forms, materials, and ages. The events and processes related to land ice, sea, rivers, wind, fault movements, and peat formation, combined with human impact over time, have resulted in a diverse gradation of these lowlands (Figure 1). Usually this variety is threatened: the relatively flat land has been flattened even further through (agro)industrial or urbanization pressures (Kluiting and Rijdsdijk 2013).

While the southeastern province of Limburg and the Campanian high ground in Belgium are characterized by hilly topography that, in places,

Figure 1 The North Sea coast: sea, surf, beach, and coastal dunes around the island of Schouwen (province of Zeeland in the southwestern Netherlands).

reaches about 350 meters and the hills in central Netherlands rise up to 100 meters, the rest of the Netherlands is a lowland area. A great proportion of the people living here have been raised with the knowledge that they live below sea level, and they experience the landscape as dull and flat. But a closer look at the flat meadows shows the careful observer that the terrain is surprisingly variable and diverse; for example, it has subtle elevation differences (in decimeters) that create sandy hills and minor curvy valleys. Conspicuous land forms—such as old sanded watercourses, crevasse systems, silted estuaries, and ledges of buried dunes—break the often rectangular patterns of the domesticated landscape. Those who use this apparently flat land either for recreational or for economic purposes must be alert to the diversity of the soil: clay, silt, sand, peat, and gravel alternate in space. They bear witness to fascinating processes related to land ice, rivers, sea, peat formation, wind, and faulting. Clear evidence of the forces of nature lies directly underneath your feet.

The largest part of the Netherlands and of the adjoining region of Flanders (Vlaanderen) in Belgium originates in the Quaternary, when it was a giant shared delta of several great rivers that transported erosional products from the European mountains to the North Sea. In the

last millennium, as a result of human-made dike systems, river deposits have scarcely contributed to land-forming processes. Soil lowering, compaction of drained peat polders, and sea level have considerably influenced the security of the coastline. On the North Sea coast the land surface is protected by a large row of coastal eolian dunes, which directly shelter the current population. This row of dunes originates in sand delivered by the sea, then blown by the wind and made into hills. In many places it is now reduced to a narrow sand dike, preserved through human effort for protection against expected sea-level rises in the twenty-first century.

Glaciation—which shifted masses of white-blue ice, hundreds of meters in height, arriving from Scandinavia—turned the original river delta upside down. The basal shifting resulted in the deposition of boulder clay and erratics and in the creation of moraines. This belt of ice-pushed ridges continues under the North Sea but is slightly eroded by waves and currents with distorted layers at the bottom of the sea, including large buried glacial valleys that are the only witnesses of ice ages. Fishermen lifted countless findings from the seabed: bones of giant deer, aurochs and mammoth, and human-made artifacts of bone and flint. More recently, remote

sensing of the seabed testified that the North Sea was an important dryland area inhabited by our ancestors only a few thousand years ago.

Wind is a characteristic feature of the landscape in the lowlands and in the North Sea; hence there are currently many plans for large wind energy parks in the area. Evidence for the force of the wind in the past is also clear. The battle against sand drift in the cover-sand landscape was not always won by the people. It so happened that sand drift transformed certain areas into parabolic dunes, not accessible to humans and declared uninhabitable for many centuries.

Faults and tectonic forces uplifted many parts of the European continent; and some of the North Sea has been heavily subsided over time (by more than 600 meters). These vertical and lateral movements of the upper earth's crust cause earthquakes that can be felt in many different places in the southern part of the region; thus in 1992 an earthquake of 5.8 degrees on the Richter scale caused considerable damage at the fault in Roermond.

Case study 2: The drowned landscape of West Brabant, Netherlands: an interdisciplinary approach

In the western part of the Dutch province of Noord-Brabant, Pleistocene sandy soils are dominant on a relatively higher platform, which slopes down gently to the north and more steeply to the west, where mainly clayey soils and remains of peat occur, lying slightly above sea level. On both soil types, agriculture was the main form of land use, although some parts of the sandy soils are covered in woods. There used to be large-scale peat quarrying in the region; it was done mainly for fuel in the sandy areas, while peat was also quarried for salt in the lowest areas. The region is bordered by the river Scheldt to the west and by the estuary Hollandsch Diep to the north, while several smaller rivers and streams drain its larger northern area. Three motorways and two railroads intersect the region today, as the waterways and many small market towns of the past have expanded. The northern clayey area remains an open landscape, but the sandy higher part has become more densely wooded over time.

The history of this region is characterized by two settlement periods, one medieval and one modern. Long-term flooding has affected the lowlands' landscape tremendously. Large parts of the flooded areas were eventually covered with a thick layer of clay, which also covered most of the medieval settlements and large parts of the old infrastructure, freezing it in time. In other parts the flooding was quite destructive: new channels were formed that completely washed away all archaeological remains. Then a second settlement period began by gradual reembanking the flooded lands. This process was completed by the end of the nineteenth century.

Specific historical features of the vanished landscape of this area have been used as key features in the plans for its redevelopment as part of the 1990s Dutch national landscape policy called 'Belvedere' (Kluiwing, Brand, and Borger 2006; De Kraker and Kluiwing 2008, 2010). The redevelopment began with an unravelling of the history of the landscape by documenting possible locations of settlements and infrastructure from the first settlement period, as well as by exploring general geological and archeological features; these were checked through remote sensing, by taking aerial photographs on different flights. After the inventory, a selection of four high-quality locations was made. Here physical geographers, archaeologists, and cultural historians went into the field or into the archives and did more detailed research on the vanished landscape. Fieldwork in oral history was carried out to explore the stories and recollections of the present inhabitants with respect to flooded villages and landscapes.

All these disciplines, combined, delivered a general picture of the history and impact of the flooding. Four key historical locations were identified, next to other drowned settlements: (1) Polre, with all archaeological remains in the subsoil still preserved; (2) Hildernisse, an excellent example of a flooded site that survives today and preserves many remains in the soil; (3) Niervaert, completely wiped out by erosive forces but still remembered for its worship of relics; and (4) Koevering, a short-lived settlement on a dyke, whose precise location still has to be worked out (Figure 2).

The next stage involved discussions between landscape experts, designers, and planners. The

Figure 2 The map of Christiaan's Groten, sixteenth century (Royal Library Albert I, Brussels), shows West Brabant (right side of the map) as part of a drowned landscape. At the front, the designer's scenario for the flooded village of Koevering is visible.
Source: From Kluiving, Brand, and Borger 2006.

kickoff was an introductory trip to the field, which was labeled “looking at grass meadows with nothing in them.” From then on four meetings and seminars were held where participants could exchange views and learn about the results reached up to that stage. The project's structure gave designers and decision makers the opportunity to form an idea of the process of research and of how various disciplines operate and to witness every step of the process. At the same time, it gave researchers valuable clues as to the kind of information that designers and decision makers really needed for the task of redeveloping the rural landscape.

The designers preferred practical information and spatial patterns with landscape as a binding factor. They did not treat the findings and the results as the researchers had expected. After picturing the development of the landscape in general patterns in time and space, the final product resulted in a “design” matrix. This matrix offers development strategies and opportunities to include spatial and historical features of the landscape at three levels: local, subregional, and regional. At the same time the matrix shows how the historical features of a vanished landscape

can be used as an inspiration for a museological scenario, as a driving force for a scenario related to the economy (building and tourism), and as part of a scenario for water. The application of the design matrix must lead to a redevelopment of the rural landscape that enlivens the drowned landscape as an important part of the heritage—one that restores the character of this lowland region (Kluiving, Brand, and Borger 2006).

Case study 3: Landscape as heritage for future directions: a transdisciplinary approach

The landscape just described—the drowned and vanished West Brabant—reflects a typically Dutch theme: the battle against water. The great diversity of geological processes and resulting landscapes is unparalleled in the world and has had its impact on the region's cultural and economic history, shaping the reality of today. Because of this, there are currently plans to seek UNESCO Geopark status for the transnational region from the Dutch Hollandsch Diep in the north to the

Belgian city of Antwerp in the south, to mark its geological, ecological, and cultural–historical richness. Global Geoparks are single, unified geographical areas where sites and landscapes of international geological significance are managed through a holistic concept of protection, education, and sustainable development.

Geological phenomena in the Scheldt region, around Antwerp, Belgium, and in the southern Netherlands testify to a dynamic landscape that shows a wide range of geological processes, from very old to very young. Local Tertiary exposures around Antwerp show 33.9-million-year-old Oligocene marine clay deposits as well as a 3-million-year-old Pliocene beach sediment witnessing coastal beach conditions. In contrast, directly north of the Nieuw-Namen site, a modern-day tidal regime is present in the (Drowned) Land of Saefthinge, where tidal flats are still being actively deposited on the flanks of Westerschelde. The Brabantse Wal escarpment is another unique geomorphological structure; it has a steep slope with an elevation difference of up to 25 m that can be followed over more than 30 km. In this slope 1.8-million-year-old tidal deposits of Tiglian age are exposed, covered by eolian dune deposits that were blown out of the Scheldt valley west of the escarpment during the late Weichselian. The hiatus between the two units is demonstrated by a thin gravel bed that reflects the long period of Middle and Late Pleistocene erosion during which the escarpment was formed through the fluvial erosion of the Scheldt river. The medieval marine flooding caused by human occupation and drainage and leading to peat shrinkage explains why large parts of the flooded landscape (most medieval settlements) were eventually buried beneath a thick layer of clay. The geological history of this region—combined with the cultural history of more than 100 drowned and buried medieval settlements and landscapes reclaimed from the seventeenth century onward by polder building—makes this a highly significant region.

The Brabant Geopark will incorporate both geological–natural aspects and socioeconomic (sustainable) development, along with innovation and cooperation between governments, knowledge-based institutes, and local business and industries. The road to UNESCO Geopark status will help catalyze innovative initiatives

and developments in the region, including the application of the design matrix. Main drivers of innovation in the region are the biobased economy, maintenance, advanced logistics, care innovation, agrobusiness, and social innovation.

Conclusion

Landscape viewed as heritage and the extremely long-term geological and archaeological story of Dutch landscape have been exemplified in this entry with three case studies at (trans)national and regional levels, from the Netherlands and adjoining Belgium; but of course the lessons are to be taken at the global level. Making people aware of the landscape around them and of possible futures has never been more important. For several years now, a scientific and even societal discussion has been taking place around the proposed concept of the Anthropocene. Many scholars agree that we currently live in the Anthropocene, even if they are still debating the date at which an epoch of this name can be said to have started (see, e.g., Waters et al. 2016); and popular awareness of the long-term nature of the process that amounted in the formation of our landscapes, as well as informing our sense of identity, belonging, and pride, will hopefully encourage a positive approach to creating a sustainable future for the planet.

Heritage and Nationalism

POLINA NIKOLAOU

University of the Aegean, Greece

Heritage is a human construction that reflects and embodies a range of human–natural–territorial interactions. In particular, it is currently widely conceptualized as a contemporary product shaped from history, a social and cultural process conditioned by its sociopolitical context (Harvey 2010; Tunbridge and Ashworth 1996, 20; Smith, 2006). Archaeology plays a crucial role in the development of the public policies and practices that define this social and cultural process. In consequence, concepts of heritage develop and change according to relationships between power and archaeology in different political units or states. In western concepts of heritage, places are defined as “historic environments” and artifacts as “cultural resources” or “symbolic capital.” These notions have been used extensively in the construction and legitimization of nations and nationalism during the nineteenth and twentieth centuries.

Nationalism is a political doctrine or an ideology consisting of a framework of ideas, beliefs, and notions that precede the formation of the nation; its aim is the nation’s political self-determination. Two main types of nationalism have been distinguished by scholars: civic or political nationalism and cultural or ethnic nationalism. The first, civic or political nationalism, emerged in the late eighteenth century and was characterized by an ideology. It associated the nation with a universal recognition of individual rights and sovereignty (Diaz Andreu 2007). The French Revolution of 1789 and the Enlightenment are regarded as key movements in the development of nationalism as constitutive of state power and legitimacy in western Europe. They promoted an ideal of replacing the aristocratic order with a more democratic conception of egalitarian community of “citizens,” which formed the basis of

the nation. The nation was perceived as a horizontal community made up of thousands or millions of participant members, with specific territorial boundaries that had the right to constitute a political entity. However, there was a conservative reaction to these ideas in the late eighteenth and early nineteenth centuries; even in Europe, let alone elsewhere in the world, not every country followed this path until later. The second type, ethnic or cultural nationalism, developed in the mid-nineteenth century, although some roots can be traced earlier, to liberal nationalism. It defined nations as units created by people who are part of the same ethnic group.

National communities are regarded in the existing literature as being “imagined communities,” because their members would never know or meet most of their fellow members, but in their minds they are part of a community (Anderson 1991, 6). Macdonald (2003, 2) argues that, since individuals could not identify with their national community through social relations, the process of identification had “instead to be cultural, a matter of shared knowledge and practice, of representation, ritual and symbolism.” Nations were founded upon the articulation of ethnic groups’ distinct heritage, on the basis of a homogeneous culture and sentiments of belonging and brotherhood. The foundations of national identity were created through common history, shared language, and distinctive cultural characteristics and customs. This process of constructing national identities entailed the acts of forgetting (or misremembering) and inventing (or rediscovering) chosen aspects of the ethnic group’s past. Thus ethnic or cultural nationalism created the essentialist and primordialist accounts that traced the origins of ethnic groups, their claims on a territory, and their cultural characteristics from remote antiquity to the present day—and these provided them with the right of self-government.

The nation’s past and its narratives of origin were articulated by the material remains found within the state’s jurisdiction. These material remains do not have an inherent meaning, but rather become meaningful and valuable through

contemporary cultural processes that identify them as material symbols of bound and exclusive national cultures. Cultural historical archaeology or (by a different name) nationalist archaeology emerged in the last quarter of the nineteenth century in Europe and legitimized nationalism by providing scientific evidence for the origins of the nation and for its continuity. It documented and interpreted the archaeological record of specific people with the aim of tracing its geographical and chronological differences from other peoples; this replaced the previous emphasis on temporal variations that was based on Darwinian evolution (Díaz Andreu 2007). The focus shifted from identifying stages of development to distinguishing particular archaeological cultures and their features. By making this shift, cultural-historical archaeology created the founding histories of the nation-states: it based their territorial rights on histories of origin and on the long-term continuities of a homogeneous culture. This process led to the justification of the political autonomy of the nation-state as it traced its ownership of land in a linear mode, from the present to ancient times. Public museums in Europe assumed the role of both educators of the citizens and historical anchors of the nation: they located and developed the distinctive qualities of national identity through linear and comparative displays (Macdonald 2003). The concept of otherness was, and still is, fundamental in the material representation of national narratives in museum galleries, since identities were constructed in juxtaposition with the perceived other. Material culture's physicality gave these notions a sense of material reality. Museums were thus transformed into poetic and political spaces whose displays were acts of cultural symbolism: they provided the scenography and stage for the performance of nationalism as the universalized myth of nationhood.

The national appropriation of heritage

Societies attribute to particular time periods an idealized historical experience that they see as the symbol of their nation-state, and the material remains from that era acquire the status of national heritage. Antiquity and its material remains have traditionally been a key anchor

point for different nationalisms and their political aspirations, as they provided a sense of historical and territorial continuity. Ireland, for example, constructed its national identity during the eighteenth and nineteenth centuries, by appealing to the ancient ideal of a pre-Christian self-governing Celtic culture at first and, next, of an early medieval culture that fused pagan Celtic traditions with Christianity. A national imagery of medieval monuments, artifacts, and picturesque landscapes was formed; it depicted a glorious and independent past, which contrasted with the colonial present of nineteenth-century Ireland. Nationalist movements in Spain (Castilian, Catalan, Basque, and Galician) authorized their causes through archaeological discourses that traced the distinctive linguistic and cultural components of their respective populations from pre-Roman times to the medieval period (Díaz Andreu 2007).

A particularly good example is Greece, where ancient material remains became symbols of the nation *par excellence*; in particular, classical architectural remains structured the topos of the new nation-state during its formation in the 1830s. Encounters between residents of the Hellenic peninsula and the traveling western European upper classes, for which Greek classicism was the symbolic capital of European Enlightenment, played an important role in the rediscovery of a Hellenic heritage (Hamilakis 2007). The support offered by the European elite to the Greek cause of liberation from the Ottoman Empire and self-determination was based on the status of Greece's classical past as an ancient entity whose glory had to be restored. This idea was appropriated by the Greek state and formed the new indigenous ideology of the Hellenic nation, a centralized and homogeneous imagined community defined by its glorious past, with Athens as its national capital. The topography of the Greek nation was founded upon classical buildings and material culture, treated as material landmarks of the new national community of Hellenism, and, along with Greek language, offered a sense of territorial and historical continuity with a classical and idealized past. Until the nineteenth century, the ancient site of the acropolis was a symbol of ancient Athenian hegemony, and during the formation of the Greek state it acquired its enduring status as the sacred symbol of democracy and of high cultural achievement. Prehistoric remains,

the Hellenistic and Roman past, Byzantine churches, Ottoman architecture, and vernacular houses retain an ambiguous status within Greek national imagery even today. The protection of ancient monuments became a priority for the new Greek state, and by 1834 all antiquities were regarded in law as national property; their conservation and the regulation of the export of artifacts were seen as matters of national duty. The centrality of this narrative within the national imagination of Greece is still evident in the claims for the repatriation of the Parthenon (or Elgin) Marbles, an eminent symbol of the Greek nation. This idea of heritage as cultural property of the national community is central to western conceptions of national identity, as it raises the issue of rights of territorial and historical ownership. Indeed, heritage restitution has become a key policy under the auspices of UNESCO among former European colonies that created new states within the twentieth century and whose material culture was collected by foreign travelers and museums during the nineteenth century. The state-sanctioned heritage management and conservation practices symbolically constitute the nation as a real and legitimate entity. The western idea of heritage as physical evidence of national cultures entails the archaeological practices of mapping, preserving, and conserving, which are authorized by national legislation all the way from early examples such as Sweden's statute for protecting antiquities—which was passed by King Gustavus Adolphus in 1630 and became law in 1666—and the Ancient Monuments Preservation Act of 1882 in Great Britain to contemporary international agreements and charters such as those of UNESCO and the Council of Europe. This relationship between archaeology and nationalism remains vibrant today, and heritage in the form of antiquities or ancient architectural remains still acts as a key anchor point for cultural nationalisms. Archaeological narratives and concepts or practices that are incorporated in heritage management policies, such as authenticity, create exclusive scientific and hierarchical categories on the basis of which archaeological collections are understood and become meaningful. In particular, the concept of archaeological authenticity becomes the cultural choice for fixing points of bounded national histories on the basis of a fundamental belief in

a sacred national and moral self that provides security in an amorphous society. The foundation of these authentic points of security is the body of knowledge that derives from an artifact's provenance, namely the archaeological context of its excavation, which fixes the meaning of material culture and positions it within the national imagery.

Even ordinary, commonplace, or typical archaeological remains can be recruited to support a national narrative. The authoritative meaning of the Bronze Age site known as Broad Down (in Devon, England) has been fixed by its official designation or production as a monument of national importance. Through heritage management schemes, statutory documentation, and interpretation boards on site, Broad Down was transformed from a typical prehistoric site used for farming purposes by local people in the twentieth century into a fragile site that required saving for future generations. The site is recorded on the Historic Environment Record (HER) and has been described as a prehistoric ritual landscape unparalleled in Devon for its national archaeological significance. This preservation process not only gave it a monumental quality but also imposed a rationality upon the site: it became a material record of constituting the national present, whose purpose is to enhance the quality of the life of the members of the nation (Harvey 2010).

Such official discourses of a homogeneous national identity in Britain can, however, be disrupted through precisely the same legal and practical processes. The narratives surrounding the Hilton of Cadboll, an early medieval cross slab in Ross and Cromarty, Scotland, have considerable contemporary symbolic capital in representing a distinctive Scottish national heritage within the supranational entity of the United Kingdom. The slab represents the high art of Scotland and is associated with a formative period in the history of the Scottish nation (mid-eighth century to early tenth century; Jones 2005). This cross slab is embedded in discourses of "belonging" and mediates the production and negotiation of the Scottish identity: it has a symbolic status as a living member of the local community. The local discourse of belonging surrounding the Hilton of Cadboll creates a relationship between the monument and the

Scottish community understood in terms of birth, soil, and kinship and expressed in claims such as “the Stone belongs to us.” The metaphorical and symbolic meaning of the monument encapsulates the idea that people belong to a place by virtue of belonging to the local community, as it embodies that place. The nation as an official power of the state constructs a hegemonic “authorized heritage discourse” that attributes an inherent cultural significance to material remains of the past and creates a consensus version of history. This approach to the past is used to support or contest the claims to territorial sovereignty of particular ethnic groups (Tunbridge and Ashworth 1996). This makes heritage dissonant and contested, a potentially divisive force that contributes to intolerance, to the marginalization of those who do not “fit” into the official national culture, and to conflict. For example, the dissolution of the Soviet Union and the consequent restructuring of the new nation-states in eastern Europe in the 1990s led to territorial and proprietary claims, which were based on the different interpretations of the ancient past and of the archaeological record. This use of the historic environment and archaeological remains can escalate to violence and may lead to the intentional destruction of heritage monuments, as witnessed in the region of former Yugoslavia during the war in the 1990s, or evidenced by the recent terrorist assaults carried out by Daesh on the archaeological site of Palmyra in Syria. Another example of how heritage, embodying different values, can be manipulated by different groups of people, for different political objectives, is the Taliban’s destruction of the statues of Bamiyan Buddhas in Afghanistan in 2001. The international community had for some time proclaimed the universal value of these sixth-century statues as part of the shared heritage of humanity. The Taliban’s radical clerics perceived them as representations of non-Islamic “impurities” that had to be eradicated from the country. The idea that the traditional approach to heritage as a valuable asset in need of preservation can lead to political conflict is also illustrated in the case of the Preah Vihear temple in modern-day Cambodia. This temple, a great example of Khmer architecture from the tenth and eleventh centuries, has become a contentious landmark of the opposing political claims between Thailand and

Cambodia. The Preah Vihear temple, along with other major temple sites, such as Angkor and Banteay Chhmar, was under Siamese possession until the late nineteenth century. The contemporary Thai government puts forward political claims that are based on the ownership of these archaeological sites. UNESCO’s listing of the temple and its immediate surroundings as a property of Cambodia in the World Heritage List in 2008, even though it covers land disputed between Thailand and Cambodia, caused a significant political controversy between the governments of the two countries over the sovereignty of the site and its adjacent area.

These examples show that cultural heritage is still appropriated by national governments to either support or dispute territorial and historical claims. Hence the consensus in current literature is that a critical understanding of heritage and of its relationship with nationalism necessitates the analysis of the nature of heritage: what it is, the process of its construction, and the cultural, social, and political work it does in current societies.

Heritage and Policy

CLASKE VOS

University of Amsterdam, Netherlands

Already from its appearance as a notion, heritage has had a political connotation. The concept emerged in Europe—and particularly in Britain, France, and Germany—within the context of nineteenth-century modernity. In this context of Romantic nationalism, new metanarratives were sought that could bind populations to a shifting sense of territorial identity and legitimize state formation. Heritage, archaeology, and the past were used to sustain these narratives and to reassert symbolic and physical borders in order to validate differences between countries and populations. Many of the newly established European states started to engage in conservation and management activities, which led to a canonization of landscape, folklore, and historic sites and to the establishment of national museums. It also led to the establishment of a preservation movement that had to make sure that the physical representations of national identity, European taste, and achievement were protected and displayed to the public. This movement advocated the so-called “conservation ethic,” a paradigm that would have a long-lasting effect on heritage policies. It stressed the trait of heritage as a limited and threatened resource and the importance of preserving resources of the past as material and scientific markers. Heritage needed to be protected for future generations, and this became an accepted and expected task of governments.

The institutionalization of this conservation ethic formed the basis of the first heritage policies. While the first legal decree to protect national antiquities dates to the seventeenth century in Sweden, the second half of the nineteenth century saw an upsurge in the development of legislation designed to protect ancient monuments and religious or other architecturally and historically significant buildings. Both architecture and

archaeology—due to their ability to claim professional expertise over material culture—took on a pastoral role in identifying the appropriate monuments to be protected under these acts and in caring for and protecting these places (Smith 2006, 19). In these first legal acts the emphasis was on preservation. This meant that heritage was defined according to whether the corresponding entity was at risk. Preservation literally meant protection of heritage from harm. It focused on the fixed quantity of historic resources, not on their perceived functionality. The idea of monumentality was leading, which meant that the cultural significance of a site, building, artifact, or place determined its use and management. This cultural significance was established by experts who valued heritage in terms of its historical, scientific, educational, and “cultural” value. The introduction of this conservation ethic was not limited to the western world. Archaeological thought and concerns over the care of cultural remains came to be exported globally, as part of colonialism and imperialism (Byrne 1991). For example, in the early twentieth century, heritage and monument laws were introduced in the Dutch East Indies and in British Indochina and India. These laws led to the selection and interpretation of indigenous heritage within western frameworks of understanding and categorization; they were focused on preserving or restoring monuments for the educational or scientific benefit of a public at home in Europe (Fienig et al. 2008, 33).

The conservation ethic remained a fundamental part of the institutionalized heritage management discourse and of political and legal frameworks in Europe during the twentieth century. This resulted from continuing Western nostalgic concerns about the potential loss of identity and traditions in an insecure present. Moreover, the rise of cultural tourism and the “heritage industry” in the 1950s and onward led to a questioning of authenticity. Additionally, the appearance of environmental concerns in the 1960s and 1970s and the rise of a general awareness, in the 1980s, that remains from the

DOI: 10.1002/9781119188230.saseas0284

past were under threat from development forces called for a renewed focus on preservation. Thus, in 1965, the ICOMOS Venice Charter was adopted, which emphasized ideals of authenticity and the maintenance of the historical and physical context of a building or site. This growing awareness about new threats to the past led to the replacement of the notion of preservation by the notion of conservation. This transition did not involve a radical break with previous approaches to heritage. It primarily meant a broadening of heritage as a notion. Not only buildings were to be preserved, but also ensembles. Furthermore, sites, buildings, artifacts, or places became selected not only through intrinsic, but also through extrinsic criteria. Thus heritage management no longer entailed primarily an investment in form, but also one in function. From the 1990s onward, conservation became related to land-use planning systems, which resulted from a consensus that the protection of the historic environment was a fundamental purpose of planning policy. This change led to the adoption of several new policy documents and legislative systems at the national and international level. While until then heritage policy had been largely the preserve of architects, archaeologists, and art historians, from that point on it was integrated in more extensive schemes of local area renovation, revitalization, and regeneration. Hence the experts were no longer the ones making decisions about preservation, but politicians and government officials increasingly started to take up this role (Willems 2010).

This increased emphasis on the functionality of heritage influenced not only the ways in which heritage was defined as this concept was increasingly broadened, but also how decisions were made, what interpretations were given to heritage, and how management practices were organized. There was a clear development toward contextualizing individual sites and monuments as part of a larger whole—the historic environment—and toward a realization that the sustainability of that larger whole, rather than the conservation of individual monuments or sites, was a key objective of heritage resource management (Willems 2010, 216). The historic environment was now being studied, evaluated, and defined in terms of its history and its present-day relevance to people. Additionally, heritage became fashion-driven.

New presents constantly asked for the imagining of new pasts in order to satisfy changing needs. At the national level, the policy context around heritage became more developed, more complex, and more explicitly linked to other policy goals, for example, economic regeneration, social inclusion, and localism. Heritage was less about tangible material artifacts or other intangible forms of the past than about the meanings placed upon them and the representations that were created from them (Ashworth, Graham, and Tunbridge 2007). Moreover, international organizations took up this broadened notion of heritage in their main conventions. In 1972 UNESCO adopted the notion of “the importance of heritage to humankind as a whole.” Additionally, during the 1980s and 1990s the Granada and Valletta Conventions introduced the so-called “landscape approach” and “integrated conservation” as a means to guarantee a more sustainable way of protecting heritage. This meant that professionals with different kinds of expertise, such as architects, landscape architects, and planners, would work together on joint projects.

Despite these trends in heritage policy and shifts in the interpretation of heritage, the conservation ethic never completely lost its relevance—not only in the 1990s, but even up to the present day. The preservation of cultural remains as markers of an uninterrupted past has continued to affect heritage policies at the national as well as at the international level. Moreover, state policies, professional expertise, and supposedly objective valuations of materials from the past are still determining most of the decision-making processes around the care for cultural remains. This trend came to be increasingly criticized in the 1990s. The hegemony of Western values in heritage management was addressed, as well as the “authorized” heritage discourse that favored professional, governmental, objective, and expert approaches to the past over subaltern and alternative heritage discourses and historical narratives (Smith 2006). The critical accounts pointed to the unquestioned conservation ethic that was underlying the heritage management approaches in the Western world and continued to determine most international heritage policies and scholarly debates. Additionally, they urged for an acknowledgment that not only the past, but also the valorization

of cultural heritage was socially constructed (see, e.g., Byrne 1991). Awareness was growing that heritage management was thus not so much about the preservation of archaeological and architectural remains as about the social values attributed to them. This prompted an appeal to take into account, in heritage management and policy, the values and interests of other stakeholders and not only those of professionals, experts, and policymakers.

In this frame new charters and policies appeared that tried to accommodate different approaches to heritage management. In the United States, for example, the Native American Grave Protection Act (NAGPRA) of 1990 introduced procedures and legal standards for the repatriation of Native American human remains, funerary objects, and cultural patrimony held in museum collections. In Australia the ICOMOS Burra Charter was revised in 1999. In the revised version, “associations and meanings” were presented as a part of cultural heritage that stood next to material artifacts. Two fundamental characteristics of these American and Australian heritage policies were subsequently adopted at the international level. The first one concerns the emphasis on heritage diversity and community participation. The second one focuses on the ideological concept of valuing the resources of the past by identifying and assessing significance and stakeholder values (cf. Lafrenz Samuels 2008). These value-based management models are currently the basis of the policies, charters, and guidelines of international organizations such as ICOMOS, UNESCO, the World Bank, and ICROM. The adoption of the ICOMOS Nara Document on Authenticity (1994), which explicitly recognized cultural and heritage diversity, is one good example of this. The set of UNESCO guidelines for managing world heritage sites by means of value-based planning is another example. Additionally, professional and ethical codes of conduct were introduced on how to incorporate the values of others in society into professional conduct in the implementation of heritage policies.

In Europe, value-based significance assessments became part of heritage policies, especially in the framework of the new legislative frameworks adopted as a result of the Valetta Convention of 1992. However, these initially paid less

attention to questions of community participation and alternative heritage values—an issue well reflected in European codes of conduct, which are primarily expressions of ethical concerns related to contract archaeology and show less interest in issues such as repatriation, human remains, and the involvement of indigenous voices and values (Aitchison 2007). Nevertheless, the last decade has witnessed important moves in this direction, illustrated for instance by the rise of community archaeology in European countries such as the United Kingdom and by the 2005 Faro Convention on the Value of Cultural Heritage for Society by the Council of Europe. Attention is increasingly paid to what ordinary people consider to be heritage; and, in line with this, there is a decentralization of heritage (or democratization, as some argue). In other words, heritage management and its affiliated policies have started to move away from fairly authoritarian and centralized decision making and toward concerns for social inclusion; local stakeholders and communities are involved in dealing with the historic environment (Fairclough 2009). This shift occurred not only because it was acknowledged that stakeholders and communities have a big influence on the sustainable preservation of that environment, but because it was recognized that they have an actual stake in heritage projects. As the title of the Faro Convention reveals, the attention has become directed to the “value of cultural heritage for society.” Heritage came to be presented as a resource for human development, for the enhancement of cultural diversity, for the promotion of values such as democracy and peaceful societies, and for the stimulation of socioeconomic growth. Different types of values were attributed to heritage: intrinsic (i.e., heritage is valuable by itself, as an enrichment to the landscape in which it is located), institutional (heritage as a catalyst for communal action), instrumental (heritage as a contributor to social objectives such as education, or to the development of certain skills), economic (heritage as an asset that can generate financial revenue for the benefit of governments), and even reconciliatory (heritage as an instrument in postconflict actions).

These changes in the interpretation of heritage policies reveal that in the past decades a paradigm shift has taken place. There has been a move from

the expertise-led and object-oriented preservation paradigm rooted in the “conservation ethic” to an inclusive and people-oriented new heritage paradigm. This paradigm shift is not yet been fully concluded. Vestiges of the conservation ethic still determine heritage policies at a national and global scale. However, there is a move to a “dialogical model” (Harrison 2012) in which heritage is seen as emerging from the relationship between people, objects, places, and practices. This model does not distinguish between, or prioritize, what is “natural” and what is “cultural,” but instead is concerned with the various ways in which humans and nonhumans are linked by chains of connectivity and work together to keep the past alive, in the present, for the future. The model presupposes an ethical stance in relation to others and a belief in the importance of acknowledging and respecting alternative angles and worldviews as a condition of dialogue. As such, it provides a way to connect heritage with other pressing social, economic, political, and environmental issues of our time. As some have argued, in this new heritage paradigm there is no place for “canons,” whether national or ethnic. On the contrary, there is a clear move away from monumental (and outstandingly universal) values. Instead, values arise locally, from the grassroots (Fairclough and Wolverstan 2013, 47). Interpretations of heritage have become ever more varied and start to serve a multitude of purposes. Amongst other purposes, heritage is seen as a factor of community building at the national, regional, and international level, an instrument behind socioeconomic development, and a means of bringing about intercultural dialogue.

More paradigm shifts might follow in the field of heritage policy in the future. Several challenges lie ahead that will ask for a continuous rethinking of policies. One of these challenges is the abundance of heritage. Due to the increasingly broad definition of heritage and the exponential growth of listed objects, places, and practices in the contemporary world, there is a risk of becoming overwhelmed by heritage, which would render it ineffective and worthless. Hence one needs to consider strategies for abandoning certain heritage sites and for offering possibilities to remove heritage from museum depots or from lists such as the World Heritage List (Harrison 2012). Another challenge is the dissonant nature

of heritage, which continues to play a role in conflicts all over the world (this challenge is by no means new). Even though heritage can be instrumental to defining communities and cementing the nation, it can also be used as a means of segregation. Even though international organizations such as UNESCO or the Council of Europe have urged for a move away from ideological interpretations of the past and toward more inclusive narratives, they continue to face many obstacles. A possible future development might be to ask for an admission that heritage is not always good or positive, and thus for a distancing from the universal value of heritage (Viejo Rose 2013). Finally, a last challenge that requires a rethinking of heritage policies is the influence of the digital age. Heritage has increasingly been digitized and made available on the web. This has made it possible for museums to display parts of their collections rarely shown to the public, has made heritage available to ever wider audiences, has introduced innovative methods of public outreach and involvement, and has made it possible to preserve photographs and texts without having to deal with the storage. However, it has also raised new questions about how to unlock the potential of digital heritage, how to deal with free access, and how to work on the web, which represents a new frontier of our global culture. These challenges—and many more could have been mentioned—reveal how heritage policy is in continuous movement, being influenced by new challenges and perspectives.

Heritage and Politics

ROSS J. WILSON

University of Chichester, UK

Heritage and politics define how the understanding of, and the values attributed to, a sense of the past are formed through negotiations of power and identity within contemporary society. Indeed, the modern concept of heritage is an invented tradition, born out of the industrial and political shifts that reformed European society from the eighteenth century onward. This concept focused on the significance of monuments and places that appeared to evoke a “national spirit.” Such Romantic allusions were drawn from the earlier work of antiquarians in Britain, France, and Germany, who had examined prehistoric, classical, and medieval artifacts as a means of demonstrating the illustrious origins of kingdoms and the inevitability of royal power. Individuals such as the French scholars Claude Fauchet (1530–1602) and François Roger de Gaignières (1642–1715) or the English historians William Camden (1551–1623) and William Stukeley (1687–1765) carried out extensive surveys of libraries, antiquities, and monuments to provide noble patrons with evidence of their ancestry and thereby with justification for their authority. Places and objects were imbued with significance and their preservation was connected to the continuance of the state and with the form and function of the nobility. The origins of the heritage movement in Europe were firmly associated with the operation of power, as evocative national narratives were formed that cemented social structures. Organizations such as the Society of Antiquaries of London (1707), the Society of Antiquaries of Scotland (1780), the American Antiquarian Society (1812), the Société des Antiquaires de France (1813), and the Gesamtverein der Deutschen Geschichts und Altertumsvereine (1852) focused on genealogy and heraldry to evidence the formation of the state as the pinnacle of achievement.

This function of the past to legitimate and stabilize the present was reiterated during the eighteenth and nineteenth century, when rapid industrialization, urbanization, and imperialism required the strengthening of national narratives as traditional structures of class, gender, and ethnicity were challenged. The American War of Independence (1775–83), the French Revolution (1789), the Chartist movement (1838–57) in Britain, and the German revolutions of 1848–49 all brought an expansion of political representation in the West and revised views of heritage. Whereas once notions of “heritage,” *patrimoine*, or *Erbe* were embedded in the figure of the monarch, now they were invested in the people, as states sought to elicit from their newly enfranchised male citizens a sense of national identity. At the outset of the nineteenth century, romanticized notions of natural and cultural sites of significance were promoted as reflective of “the people.” Literary figures such as Johann Wolfgang von Goethe (1749–1832) or William Wordsworth (1770–1850) extolled the virtues of both national culture and tradition, as “heritage” became emblematic of the state. As part of this process, conservation and preservation movements took place during the nineteenth century in Europe and the United States, as a reiteration of what was important for the nation. In France, the title of *inspecteur général des monuments historiques* was created in 1830; the person appointed to this position had to catalogue the historical environment in the country while the nation veered between a monarchy and a republic. With the establishment of the Third Republic from 1870 on, these *monuments historiques* served as memorials set up by the nation for the people.

The conservation of natural sites followed the same trajectory as cultural heritage: governments concerned with the loss of places of collective identity set legislation to protect areas of “wilderness.” Natural areas were assumed to possess the character of the nation, so their protection from development enabled the survival and promotion of a singular nationalism. In the United States, the Yellowstone National Park Protection Act (1872)

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0285

enabled the preservation of a large tract of land in Wyoming, Montana, and Idaho and in the process defined a distinct “American” character. The legislation protected sites considered to reflect the values of the nation during the late nineteenth century, when the processes of urbanization and mass immigration had been perceived by nativist politicians as a dilution of this character. The democratic state was strengthened through this protection of heritage in response to the challenges of modernity, since the government drew upon a sense of the past to appeal to mass electorates. As western countries used legislation to protect natural heritage, the notion of heritage as a universal good was established during this era. The discourses associated with the formation of legislation and modes of protection in the nineteenth century serve to underline political identities and structures of government while presenting heritage as politically neutral. Heritage as a conservative influence on society preserves political and social systems as much as it ensures the protection of landscapes, sites, and objects of significance. As such, heritage forms the basis of the emergence of democratic nation-states in the West during the nineteenth century (Silverman 2011).

The association of heritage with nationalism ensured that the former served as a means of exclusion and as a means of establishing common points of identification. The concept of heritage formed in the nineteenth century was structured by notions of class, gender, and ethnicity. In Britain, France, and Germany as well as in the United States, to look upon heritage in the form of a landscape, place, or object and to appreciate it fully as a category of value required a male middle-class European identity. With the imperial expansion of major powers in the late-nineteenth century, notions of heritage were used to support a colonial politics that enabled and supported the exploitation of peoples and resources in Africa, the Americas, Asia, and Australasia. The removal of cultural artifacts from colonized areas across the world and their display in the West develops significantly from the eighteenth century on. For example, the military campaigns of Napoleon Bonaparte (1769–1821) in Egypt (1798–1801) triggered a fascination with monuments and artifacts from the ancient sites along the Nile. These were displayed in public places and in museum

collections where audiences could marvel at the past achievements of former empires. This use of heritage supported an imperialist structure of power, because the current inhabitants of these sites were encouraged to sever any sense of connection with this past: the empires of Britain and France appeared to be the rightful heirs of such illustrious forebears. The removal of artifacts (including human remains) from indigenous peoples was also made to serve as the base for a classificatory system of human racial types; cultural heritage was employed as evidence of a social evolutionary scale. The display of objects from traditional societies was used to reinforce notions of racial superiority. At the Great Exhibition of 1851 in Hyde Park, London, the display of people and objects from imperial possessions provided an image of British, European, and western hegemony.

The use of heritage to reinforce nationalism and imperialism in the nineteenth century indicates the significant political role of representations of the past. In the twentieth century, this function of heritage was consistently present, as the turmoil of conflict and dictatorships witnessed the appropriation of heritage to secure power. In Nazi Germany (1933–45), prehistoric and medieval monuments and sites were used to promote the racist ideology of the state. The way this continued the established modes of representation rather than marking a departure from them reiterates the function of heritage within modern society. As a tool of conformity, the recognition and protection of the past establishes the relationship between the individual and the state. It is this connection that has been challenged by the global political changes that have occurred after 1945. In the wake of total war, genocide, and the deaths of millions of civilians during World War II, the connections that societies possess with their own past and with that of others have become a far more contested area of study. With the rise of internationalism, democracy, and postcolonialism, the political function of heritage has been utilized to disrupt western hegemony (Makuvaza 2014). This process can be observed for instance in Ghana, which achieved independence from Britain in 1957. In the same year, a national museum was founded to house the nation’s artifacts and to emphasize its distinctive character

as a modern state. Indeed, the museum was created by the passing of the Ghana Museum and Monuments Board Ordinance 1957, a piece of legislation that also enabled a protective framework for sites of national importance. In India, the granting of independence in 1947 saw the reinvigoration of imperial organizations such as the Indian Museum in Kolkata or the National Archives of India, and the formation of new institutions such as the National Museum in New Delhi, all designed to promote Indian national identity through cultural heritage.

While cultural heritage has been mobilized in this context as part of a nationalist objective, it serves as a response to the undermining of colonized peoples, which occurred as a consequence of imperialism. Conversely, this postcolonial, nationalist use of heritage has developed alongside the formation of an international agenda within heritage practice. The formation of the United Nations Educational, Scientific and Cultural Organization (UNESCO) as a specialized agency of the United Nations in 1945 brought the politics of globalization to what had been a nationalist program within cultural heritage. The Nubia Campaign in 1960 saw cooperation between Egypt, Sudan, and other nations across the world in protecting ancient sites from the development of the Aswan Dam. The promotion and preservation of heritage stimulated the development of international protocols, which in turn have encouraged the concept of world heritage. In 1978, UNESCO's World Heritage Committee began to define world heritage sites, which are regarded as possessing global significance and afforded protection through international treaties. In this manner heritage becomes a tool for global cooperation and diplomacy, as nations recognize the value of the past from other areas of the world and each is accorded the same significance. Heritage acts as a tool of diplomacy, as a means of discourse between nation-states that promotes cooperation, development, and tolerance (Albert and Ringbeck 2015).

However, the concept of *world* heritage and the use of world heritage site status to encourage tourism and economic development have been regarded by critics as a means of alienating indigenous groups from their past while promoting an elite, exclusive global community.

This assessment has grown out of a wider critical perspective in the 1980s that addressed the role of capitalism and of the state in preservation and conservation initiatives (Lowenthal 1985). This critique stated that the presentation of the past within the public sector was an exercise in corporate culture and reduced heritage to a shallow, facile copy of reality that could then be rapidly consumed by its audience. The Disneyfication of history was mentioned by scholars who drew upon a postmodern assessment that emphasized the lack of meaning in late-twentieth-century heritage. The function of this mode of representation within a capitalist society was assessed by scholars to be one of enforcing political passivity while the rights of individuals were ameliorated elsewhere. The analysis of the consumer model of heritage mirrored broader developments, which highlighted the exclusory nature of heritage. According to this assessment, issues of class, gender, and ethnicity had all been implicitly or explicitly removed from representations of the past; heritage was regarded as a vehicle for political suppression. Hence scholars sought to undermine the idea of what constitutes heritage and to argue for a greater variety and pluralism in the public understanding of history. This process of democratization within heritage studies has enabled multiple agendas to emerge that address historic and contemporary injustices.

Heritage as a means of obtaining social justice has become a central component of critical heritage studies over the past two decades. This politically aware approach has sought to explain how groups and communities have been excluded from society through the operation of "heritage." This attempt has also brought a recognition of the wider traditions, practices, and performances that constitute our relationship with tradition (Smith 2006). This disrupts western and predominantly male forms of heritage, which have structured the formation of the nation-state from the nineteenth century. Moving beyond the material base of heritage to encompass the intangible enables a plurality of voices and perspectives to be better heard and seen. The notion of "intangible heritage" has been recognized by UNESCO since 2003, and its employment by scholars has created a greater political role for the field, as this notion disrupts national, gendered, and class-based assessments of heritage. A more inclusive model

of heritage has been formed through a study of both tangible and intangible forms of heritage. However, while growing awareness of what constitutes heritage enables the formation of political identities that might lead to further democratic modes of governance, the ever-expanding list of objects, sites, and landscapes worthy of protection might result in social stasis, as change and adaptation are stifled by a reified sense of heritage.

The preservation of heritage raises broader issues regarding environmental change, sustainability, and adaptability, given that heritage studies are at the center of political debates on how human society continues to live as part of the wider environment (Harvey and Perry 2015). This position has provided heritage studies with a significant role within political ecology, as climatic change threatens the stability and preservation of buildings, places, and cultural practices. However, rather than focusing on the threat posed to heritage sites by environmental issues, heritage can also serve as means to create new political identities, which adapt to loss and alteration because relationships with the natural world in the past can provide new modes of engagement. As the climate alters, the remembrance of our past environment could be the basis of new relationship between humans and nature.

Therefore, within contemporary heritage studies, heritage in its political aspect can be defined as a mode of engagement with the past, the present, and the future that influences four distinct areas of concern:

- national identity, internationalism, and governance;
- communities, dissonance, and empowerment;
- human rights, social justice, and equality; and
- environmentalism, ecology, and sustainability.

These four areas reflect alterations in the discipline as it has moved from being the preserve of the nobility, the instrument of control of the state, and the tool of the body politic. Politics underlines the formation of heritage from the seventeenth century to the present day. The continued role of heritage in the contemporary global society is born out of this relationship with politics. The significance of heritage is not due to

a universal human quality that emphasizes the past and extolls tradition but to the relationship between individuals, communities, and the state: heritage is a political matter. The representation or examination of heritage constitutes an engagement with the political structures that define identity, power, and place in the modern era.

Heritage and Society

INGER BIRKELAND

University College of Southeast Norway, Norway

Heritage and society

Heritage is something that human beings engage with, communicate about, and also make a living from. It has been argued that heritage has always been with us and that it has always been social by being produced by human beings (Harvey 2001). Heritage is everywhere. It is profoundly human to engage in meaning-making activities concerning the material remains of the past. This means that heritage can be everything to everybody. There is nothing intrinsically modern about heritage being social, because all societies at all times make use of their pasts. There can be no heritage that falls “out” of society or is not related to society, so the topic itself is all-embracing, if not defined.

Heritage cannot be viewed separately from its contexts, from its natural and social environments. In social science, a contextual concept of heritage is important. The contextual character of culture is understood through references to a situation in time and place. The relationships between heritage and society can be understood along three dimensions: (1) heritage is internal to society; (2) heritage is socially constructed; and (3) heritage constructs society. Society creates heritage and heritage creates society. It is important to make this two-way relationship explicit to researchers, practitioners, and policymakers alike.

First, heritage is internal to society in obvious and less obvious ways. Heritage is internal to society by appearing as a social phenomenon and as a cultural process. Typically, the term *heritage* often appears in phrases like “cultural heritage” or “natural heritage” and not alone. Both natural heritage and cultural heritage specify that heritage is part of the human domains of reality. Further, the concept of culture is a key to understanding the relationship between heritage

and society. Society is not identical with culture, while culture can be viewed as an aspect of society. Culture refers to the negotiated content of meaning that exists within human societies, and as that which makes communication and meaning possible in society. This shared content is like a map of meaning, a system of language, symbols, and knowledges used by humans. It is through culture, through communication, that societies give meaning to heritage.

Another marker of the social character of heritage is the human or social importance of preservation or conservation—the fact that humans and societies have developed institutions, regulations, and practices in order to preserve or conserve selected remains, traditions, or knowledges from the past. Here there is no intrinsic difference between natural and cultural heritage, as all remains are from the past—tangible, intangible, and digital—with relevance or significance to human societies. Humans ascribe meaning to things, landscapes, memories, artifacts, places, sites, and so on in the present through relationships with remains inherited from the past.

Second, as heritage is social, it is socially created and a product of human societies. This means that heritage is created by human beings and social institutions. The idea of a museum, for example, stems from middle-class society, where the museum was an instrument of national pride and power; particular connections came to exist between the museum idea, class, and progress (Bennett 1995). To understand heritage, we must view it in relation to the social actors and institutions involved in its production and reproduction. So, instead of studying heritage objects and artifacts, we are studying the heritage process or what is commonly referred to as *heritagization*, which refers to practices and processes that create heritage, whereby ownership, knowledge, and recognition are created by local communities and the wider society.

Heritage is interpreted and communicated by humans within particular contexts from particular perspectives (Smith 2006,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0287

Kirshenblatt-Gimblatt 2006). As societies change and develop over time, it is obvious that the definition of what constitutes heritage changes; what is understood by the term can also change over time and vary between different groups. Societies differ and every society has a different relationship with its past and with the uses of heritage. Within societies, different groups and individuals will interpret heritage in different ways. Some societies or groups within societies have troublesome pasts, and sometimes choose to forget parts of their pasts. There is no absolute definition of heritage in society, so a good start when seeking to analyze and manage heritage is to situate it within its social context and look at its particular and often contested understanding in that context.

Consequently, what heritage is will differ. The nature or essence of heritage, the objects and subjects of heritage are established by ascribing value. Valuation is a social process. The value of any type of heritage is not self-evident but socially constructed. This means, further, that valuation is perspectival. There is someone doing the valuation on the basis of particular values, perspectives, and interests, and valuation is deeply connected to the workings of power in society. It is important to gain a good understanding of the politics of valuation, of actors and interests, of policy contexts, and of how heritage makers have contributed to shaping or making heritage with particular forms of value. What counts as valuable heritage is, consequently, a contested domain in all societies, both democratic and totalitarian. Values are implicitly present when asking questions such as these: Do we want a museum's identity and purpose to be a political symbol for the national heritage elites? Should the museum reflect the worldviews and the *nature* of the museum's objects and subjects? Further, valuation of heritage is not relevant just for purposes related to the present. Valuation is deeply connected to imaginary futures.

This means that there is no single correct and true understanding of what heritage is or should be. There are many stakeholders in heritage, ranging from local populations, visitors, and tourists to enterprises and businesses, organizations, policymakers, and public administration.

Third, as heritage is a social phenomenon, heritage takes place, is shaped, and has effects in a world—in a social world—that consists

of social relations, action and interaction, and social processes. What does it mean that heritage constructs society? Heritage can in this sense be viewed as a landscape, a collective history and geography, a structured totality—much like a *habitus*—that generates meaning and action. Heritage has important effects on human societies. It is central to identity development, to enhancing human well-being and the quality of life, and to improving the way places and landscapes are perceived. It is said to revitalize society, strengthen democracy, and contribute to a more educated and critical public and can be used to improve governance and economic growth. Heritage engages the general public in many ways. In a European context, the Faro Convention places heritage firmly in the hands of human beings by defining heritage a benefit for humans and by linking it to human rights and fundamental freedoms.

Heritage thus contributes to social, cultural, and economic development as well as to sustainable development, which means that we cannot separate development from its contexts. In this sense heritage is also an aspect of development, not only an object or resource for development. As an aspect of development, heritage is always present in human ways of life and livelihoods, so that a people-centered heritage builds identities and supports individual and collective memories and cultural sustainability (Auclair and Fairclough 2015).

The benefits of heritage are well documented, but so are the ways heritage also reproduces social, economic, and cultural differences around the world. For example, the nominations for UNESCO's World Heritage Convention are not ideal or absolute, but related to particular national nominating committees. The end result is that we have a geographically uneven enlisting of what is considered to have outstanding universal values; thus global differences in power are reproduced. Heritage is deeply connected to globalization processes, to how technological and economic development contribute to shaping social life, and to the way power works in society.

Important changes regarding how heritage has been viewed and how it is valued in society have taken place during the past 40 years—the period following the intensification of the globalization of the world economy after the 1970s.

First comes the change from understanding heritage through noncontextual approaches to using contextual approaches—or from object-oriented to constructivist and relational approaches. One tendency has been to focus on constructivist approaches and the social aspects of heritage, looking at heritage in a social context rather than focusing on it as objects with universal or inherent values. This change was influenced by the development of critical heritage studies, and in particular by Laurajane Smith's (2006) *The Uses of Heritage*, which challenged western classical definitions of heritage focusing on the consensual, the pleasing, and the tangible (what she calls the authorized heritage discourse). The new discourse placed a focus on social and societal aspects such as memory, performance, identity, intangibility, dissonance, and place. With provoking sentences like "There is, really, no such thing as heritage," Smith (2006, 13) drew attention to the ways heritage has meaning to everybody in society, and not only to experts and to cultural elites, who traditionally were those who defined what and how to conserve and what to value as heritage.

The debate led to a change from understanding the objects of heritage as "dead" or without agency (heritage as artifact) to understanding them as "alive" or animated by being "social" in a much wider sense. Going one step further, with a different approach, we find ideas of heritage as social in a wider sense, where heritage is relational, collaborative, dialogical, and interactive: it interacts with human and nonhuman agents and subjectivities (Harrison 2015). If heritage is a process, the becoming of heritage is created through natural and cultural processes and represents a totality endowed with diversity and multivocality, an endless, renewable resource open to new interpretations. In this approach, the distinction between what is considered social and what is considered natural or nonsocial is blurred or transcended totally.

The second major change in recent years is a slightly different one. From an economic point of view, heritage has historically been considered a cost to society. Heritage has been a cost in public budgets and a moral duty of democratic, western societies. Recently we have witnessed a shift whereby heritage appears as a vital resource in society. This is a huge change in thinking,

which means more than simply viewing heritage as a means of improving economic performance in a European perspective. It involves turning away from a concept of conservation isolated from use to a new paradigm, which could be described as preservation through use. In this new paradigm, heritage is valued as something profoundly important for improving not only the economy, but also people's lives and living natural environments. Heritage can play an important role for society's overall sustainable development.

This shift reflects the new economy of late modernity, where places, objects, services, institutions, and sites are assimilated into world economy through commodification and place branding. The difference between politics and economics is erased, leaving economics to the ideology of neoliberalization. The marketization of the museum as an institution can transform the museum into a business enterprise where the vocabulary of heritage practitioners changes from exhibition to product. In this scenario, many heritage institutions have or will have more in common with theme parks like Tivoli in Copenhagen and Disneyland in Florida than with the nineteenth-century object-oriented museum.

One challenge for the future is to find ways to frame the relationship between heritage and society that insist on not reducing society to a neoliberal economy and the agents of heritage to producers and consumers. And in the big debate that goes on in our societies as to how to make the world a more sustainable place, in particular after the financial crisis, it is important to find new ways to connect present heritage values to future heritage values.

Current emphasis in research and theory underlines several important aspects, where one common theme is an interest in discussing heritage and society across the nature–culture divide and across the divide between tangible and intangible heritage.

This interest can take many directions. One concerns how global climate change affects the relationship between heritage and society (Solli et al. 2013). How are we going to understand heritage today and in the future, when the world's population needs to find solutions to global social and economic inequalities, environmental problems, and climate change? The division between natural and cultural heritage—which has been

institutionalized in much heritage discourse in society—becomes completely artificial in the light of what some argue: that we not are living in a new geological epoch called Anthropocene. Global climate change is a topic that was monopolized by economics and systems thinking but that affects all of society, and many social and cultural processes are central to climate change by influencing how this phenomenon is perceived and understood. Global change affects the understanding and the definition of heritage and how societies and governments deal with it, which means that heritage policies are often dealt with together with policies for sustainable development.

At a more profound level, the modern worldview was conditioned by a dualist construction of reality, a view in which nature and society were seen as unrelated and had nothing to do with each other because their constitution was different. Society was seen as made up of human beings who think and act intentionally, while nature was most often understood as consisting of various determinate sets of objects and objective processes independent of subjectivity. The objectification of society that came with modernity meant that nature, or the natural environment, was objectified and domesticated. Researchers in the social and human sciences very easily focused on issues of social and economic injustice, power, and class relations within society, while the deeper power relations between nature and society were overlooked. Now this has changed, and in ways that affect how heritage is understood.

The emphasis, in research and theory, on heritage and society is now expanding (Harrison 2015) in a direction of greater openness regarding what and who can “own” agency (operating with both human and nonhuman actors). New developments are coming from various form of postnormal science, strong structuration theory (SST), the sociology of scientific knowledge (SSK) or actor–network theory, postphenomenology, posthumanism, postnature theory, and nonrepresentational theory, all of which influence heritage studies and research around the world today. Thus the most interesting work in heritage research for the future reflects this bridging between the social and the natural sciences (Castree 2005) by stressing human relations with nature and how human beings make sense of nature. This implies

that the transformation of heritage into a vital resource for society requires an understanding of the relationship between nature and society as a power relationship.

The questioning of the Cartesian dualism that led to the division between nature and culture, body and mind, and so on has also led to new discussions concerning another problematic topic in heritage and society, namely the relationship between tangible and intangible heritage. Heritage has both tangible and intangible aspects, which often represents a problem for heritage research and management. In one sense, heritage consists of material or tangible culture, and all the ways human beings are related to their material and physical surroundings through cultural landscapes, objects, artifacts, places, and spaces. In another sense, heritage has intangible aspects through the immaterial manifestations of society over time (living cultures). Now this requires seeing the tangible and the intangible as co-implicated, so that it is impossible to study them in isolation.

To conclude, the relationship between heritage and society can be viewed in narrow or broader terms. Heritage can be a topic complex and wide enough to include everything; it can be as wide as a landscape, since it reflects the way humans have cared for, built in, and exploited their surroundings over time. From a critical perspective, it is important to acknowledge that heritage is social and represents sites of struggle; thus it reflects how society is stratified and differentiated—which means that the question of what heritage is will have as many answers as there are social groups, classes, nations, and identities around the world.

Heritage and Sustainability

ELIZABETH AUCLAIR

Cergy-Pontoise University, France

Against the increasing environmental, economic, and social crisis that our societies are facing worldwide, various approaches to foster sustainability are currently being investigated and heritage seems to be taking a significant place among them. Heritage is obviously part of culture. It supports and transmits culture and at the same time it is a socially constructed object. In recent years, scholars and policy makers have analyzed the relation between sustainable development (SD) and culture, considering culture in its different meanings (heritage, landscape, arts, traditions, ways of life) and underlining both the advantages and the risks of this growing relationship (Auclair 2014). This articulation can give opportunities to many practitioners, in the arts and the culture sectors on one side and in the SD sector on the other, to reflect on their own actions, modify their practices, and develop new partnerships.

Nevertheless, limits come from the focus put on market-oriented culture and on heritage strategies, and from forms of instrumentalizing culture. Although many actors are still battling to integrate culture into the national and local agendas, notably due to a general decrease in public funding, culture is nowadays frequently acknowledged as a component of sustainability, either as the fourth pillar of SD or as a transversal or a fundamental dimension of it. A number of major cities throughout the world (e.g., Lille, Barcelona, Belo Horizonte, Bogota, Malmö, Milan) have adopted Agenda 21 for Culture, which was defined in 2004 by the United Cities and Local Governments (UCLG) association in order to establish links between culture and SD policies. More recently, during the UCLG Culture Summit that took place in 2015 in Bilbao, “cultural heritage as a driver of sustainability”

was emphasized. The theme of UNESCO’s 2013 Congress in Hangzhou (China) was “Culture: Key to Sustainable Development,” and its concluding statement strongly acknowledged culture as a central element of sustainability. Many academic works have explored under what conditions culture and heritage-based actions can contribute to sustainable territories (cities as well as rural areas) and improve the living conditions of the population (Auclair and Fairclough 2015; Dessein, Battaglini, and Horlings 2015; Hristova, Dragičević Šešić, and Duxbury 2015). However, criticism has been raised in recent years against the notion of SD, by underlining the limits of the concept; the single word sustainability seems nowadays to be preferable, and the idea of cultural sustainability has been explored and outlined as a fruitful concept (Dessein, Soini, et al. 2015). New theoretical models are emerging and innovative practices for sustainability are being tested by international and national bodies as well as by local actors, civil society, and the citizens themselves. Most of these theoretical and practical developments aim at establishing citizens as key actors and agents of change.

In order to reveal the growing relationship between heritage and sustainability, the recent evolutions of these two concepts will first be highlighted. This will be followed by an analysis of three main cross-cutting issues: heritage as place-based approaches, heritage as people-centered processes, and heritage as local democracy practices. To conclude, some alternative theoretical and practical pathways will be highlighted.

Sustainability and heritage: two major challenges for the twenty-first century

Definitions, perceptions, and representations of both sustainability and heritage are constantly evolving. Criticisms of the concept of SD have increased, pointing notably to the fact that this concept is embedded in a neoliberal economic model and is based on the dogma of unending

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0288

growth; hence the predominant weight of economic and financial interests makes the three pillars system of SD (economy, environment, social) quite problematic. There seems indeed to be a growing tension in our societies between two driving forces: on one hand, a prosaic approach, based on pragmatic, technical, and materialistic values; on the other, a poetic approach, based on sensitive, symbolic, and spiritual values (Morin 2007). It appears that, despite a number of international summits, nation states seem unable to take common decisions to prevent the aggravation of social exclusion and inequalities inside as well as between countries, or the increase of climatic changes and environmental degradation. Many works demonstrate that there cannot be infinite growth on a planet with limited physical and geological resources. Economists such as Serge Latouche (2007) have investigated new models of society without growth. Alternative theories, models, and practices for sustainability and social well-being have therefore emerged, founded on the notions of “degrowth,” “slow” attitudes, “transition” initiatives, and on the spreading concept of a “commons.” In addition, economic and financial criteria such as gross domestic product (GDP), used for comparing economic progress and defining levels of wealth, are nowadays subject to critical debate. GDP essentially measures market-oriented activities and monetary exchanges, and scholars, civil society organizations, and local governments are therefore currently conducting theoretical and practical work to define other indicators, which are not based on competition, performance and profit making. The aim is to identify values for the well-being of present and future generations and to establish new models of sustainability on the basis of people-centered approaches and qualitative criteria, notably cultural indicators. These theories connect with social and political movements (Antiglobalization, Occupy, Indignados, Places, Global Justice, Buen Vivir) that have arisen recently in various countries in the world and the fight for social justice, local democracy, and greater environmental awareness being supported by local actors in the civil society.

All these ideas and movements raise a series of issues related to our fundamental needs and expectations. What are our present needs? What kind of society do we wish to leave behind for the

next generations? What can be the role of culture and heritage? What have we inherited from the past, and what will we be able to transmit onward? What are the relevant tools for defining, preserving, and creating our cultural resources? Who has the legitimacy to drive culture- and heritage-based actions? What should the role of the citizens be? These crucial questions contribute to explaining why heritage has become a major dimension of sustainability, as an issue not only of preservation but also of creation, adaptation, and resilience to changes (Auclair and Fairclough 2015).

The notion of heritage has undergone noteworthy modifications in the past decades. Heritage is no longer considered a collection of objects and sites to identify, conserve, and protect, taken charge of solely by “experts,” but it is seen as a place-based, people-centered process that articulates key values of history and memory, identity and place, democracy and citizenship. These approaches are inserted in a number of international documents: the Florence European Landscape Convention held in 2000 (visit <https://rm.coe.int/1680080621>), the Faro Convention on the Value of Cultural Heritage for Society held in 2005 (visit <https://rm.coe.int/1680083746>), the UNESCO 2005 Convention on the Protection and promotion of the Diversity of Cultural Expressions, the UNESCO 1972 and 2003 Conventions on tangible and intangible heritage, and the UNESCO 2011 Recommendation on Historical Urban Landscapes. Most of these texts insist on broadening the concept of heritage, on taking into account tangible and intangible heritage, arts, customs, and behaviors as well as natural elements, objects, and buildings, and on developing inhabitants’ participation. This means acknowledging the diversity and plurality of individual and collective identities and encouraging dialogue and exchanges between generations, between neighborhoods, and between communities in order to promote sustainable territories.

Heritage as a place-based approach

From the start, sustainable development was embedded in a framework that links the local and the global levels (“think global—act local” was

one of the SD principles). However, there seems to be a current shift in SD's theoretical setting (as well as in that of many other policies), characterized by growing emphasis on the local level, which is seen as the basis for alternative ideas and solutions and as the most efficient level for action (Auclair 2011). According to the specificity of the context, the term "local" can relate to a community, a neighborhood, a village, a town, a region, and so on. The term "relocalization" is frequently used in expressing this turn and in developing place-based, transversal approaches to local activities. The objective is to put into practice bottom-up methodologies that are based on the participation of the population and of local actors. Facing the limits and risks related to globalization (homogenizing influences and destruction of traditional cultures, threats on the viability of locally made products, and marginalization of certain territories and countries), the aim is to promote values of "localness."

At the same time, attention is given to enhancing the connections with other communities and the links with other territories, in order to prevent identitarian closure and its dangers of fundamentalism and extremism. Heritage as a driver for sustainability means encapsulating heritage into wider policies, linking it with culture, education, social action, health, ecology, city planning, and so on. Although heritage is commonly seen as a tool for local development, particularly through tourism, many works emphasize the social aspects of heritage, and not only its economic benefits for the territories. One of the problems seems linked to targeting for support only those cultural and heritage policies that provide economic or communication benefits. In the growing competition between cities and between regions, local politicians are undeniably looking for strategies that should be economically profitable and efficient in terms of territorial marketing and branding. Considering heritage as an essential resource for local communities presupposes adopting a large definition of this notion, one that encompasses urban, industrial, and rural sites and landscapes, together with traditions, languages, and crafts. It also means acknowledging and articulating national, local, and indigenous cultures and taking into account world heritage sites, national heritage, as well as ordinary, everyday heritage. The issue is to recognize the heritage of "home,"

and not only that of the "holidays." The challenge is indeed to balance two strategies, which can appear complementary or conflicting: on the one hand, heritage for tourists and visitors; on the other, heritage for the local population.

Heritage as a people-centered process

By identifying what counts and what makes sense for the inhabitants, heritage-based strategies renew principles and methodologies applied to local development. The Faro Convention appears to be a key factor in this approach of linking heritage and sustainability, as it puts first people's values, aspirations, and needs and promotes the diversity and plurality of their views and values. It explicitly mentions everyday, ordinary living heritage as a noteworthy category—and not only the historical, aesthetical, and remarkable elements identified by "experts." Heritage as a lever of sustainability means supporting local strategies that incorporate emotions and attachment to one's living place. It supposes moving beyond profit-driven approaches, which tend to use heritage only as a tool for the embellishment of cities or as an instrument for economic development. The aim is to preserve heritage not for its own sake, but for explicit and broad social benefit (Fairclough et al. 2015). The values of heritage-based actions for people and communities are plentiful: heritage can contribute to enhancing local identities and places of belonging, to encouraging cultural diversity and intercultural dialogue, to fostering access to culture, and to developing cultural rights and human rights. The aim is to increase social inclusion, equality, equity, and fairness. The Faro Convention also insisted on increasing the role of citizens in defining, deciding, and managing their cultural environment. Besides, in the words of the convention, "everyone, alone or collectively, has the responsibility to respect the cultural heritage of others as much as their own heritage" (Article 4b). Responsibility was defined by the German philosopher Hans Jonas as a moral principle and as a major component of SD (Jonas 1984); he was indeed concerned about social and ethical issues, and part of his work focused on the future of the planet and on the conditions of human

survival. Jonas showed the responsibility we collectively have toward the present generations, but also toward future generations. Responsibility and rights appear as fundamental standards in heritage policies and practices. However, responsibility for heritage cannot be the exclusive domain of experts or public authorities. It introduces new governance strategies and tools, and supposes democratic participation designed “to involve everyone in society in the ongoing process of defining and managing cultural heritage” (Preamble to the Faro Conference; for both quotations, see <https://rm.coe.int/1680083746>).

Heritage as local democracy

Heritage, seen as a place-based, people-centered strategy for sustainable territories, leads to inventing new governance tools and original participatory methods for the co-construction of policies and actions based on values of sharing, exchanging, and co-deciding. However, while there seems to be a certain consensus among scholars and professionals to consider heritage as a fundamental resource for societies, this statement can lead to different levels of democratic engagements and practices. Linking heritage and sustainability supposes places and communities that are involved in heritage issues and in the preservation and valorization of heritage. Various activities are proposed, such as conferences and debates, pedagogical events for younger children, participatory exhibitions focusing on ordinary, everyday heritage, or “urban walks” involving inhabitants as local guides. These actions contribute to the inhabitants’ greater acquaintance with the different neighborhoods of the city and better understanding of them; consequently they can foster citizenship by changing representations and by stimulating pride in or attachment to the place where people live. Hence, implementing innovative governance methodologies for heritage management implies often quite significant changes: it means redefining the roles of the different actors involved—state, local governments, private stakeholders, civil society, and inhabitants. The challenge is to stimulate the values of local democracy among all the stakeholders. Promoting empowerment and developing capabilities, for

example, can be used as means to encourage participation. Governance methods linking experts, public authorities, and inhabitants can help them to reach successful levels of co-responsibility and co-construction. Besides, considering heritage not as a collection of objects but as a whole process that encompasses past and future requires adequate changes in policies in order to articulate short- and long-term perspectives. This leads to implementing governance strategies and tools for preserving and safeguarding heritage, but also for supporting changes, transformation, and adaptation. The recurrent use of the prefix “post” (e.g., postmodern, postindustrial, postcolonial, post-carbon) illustrates the doubts and questions we have about the future of our societies, the “after” being often seen as worse and less sustainable than the “before.” So, in these times of uncertainty, the fundamental challenges for heritage, considered as a means to enhance the link between past and future, is to support human dignity, emancipation, well-being, freedom, and peace.

Investigating alternative pathways

Heritage is widely acknowledged as an essential dimension for every community or society, and it can be found at the core of many ongoing issues. Indeed, in a context of intense competition between territories, a major challenge is to limit the instrumentalization of heritage in mere territorial branding and economy-based issues and to support policies and activities that sustain individual and collective well-being. While many alternative theories and practices are currently developing among scholars, social movements, and grassroot initiatives, the two related concepts of degrowth and the commons are gaining an increasing audience: these notions seem to be establishing a new framework for dealing with heritage issues.

Although the term degrowth can still appear provocative in times of massive unemployment and social exclusion in the global North and of considerable poverty in the global South, it relates to a model that fosters environment preservation, promotes conviviality, social justice, and democracy, and enhances the values of localness. Likewise, the spreading concept of

the commons is a consistent tool for preserving vital resources such as natural ones—but also knowledge, culture, tangible and intangible heritage—and for supporting collective responsibility and self-organization. The purpose is to limit enclosure, privatization, and the exploitation of essential resources. So, between market-oriented strategies focused on consumerism and economic growth at one end and centralized top-down public policies at the other, the commons approach appears as a third path for setting citizens as key actors in all these changes. The commons exist when people—forming a community—identify and define a resource as a common, when they decide, together, to take charge of this resource, which they consider fundamental, and when they establish collective rules and practices for a fair, ecological, and democratic use of it. Hence commons are not solely elements such as forests, or heritage “objects” that need to be protected and conserved; they suppose a process based on participation, transparency, and equity. So, considering heritage as a common means taking into account the cultural needs and aspirations of the inhabitants for mutual social benefit. However, this shift in heritage paradigms appears in many cases as an ongoing process. Indeed, it relates to a theoretical and practical turn, which implies new ways of considering and defining heritage and supposes alternative governance tools and methods. These changes will take time.

Heritage and Value-Based Approach

ANDREW G. McCLELLAND

Maynooth University, Republic of Ireland

That society will seek to conserve only that which it values is a truism underpinning a value-based approach to heritage. Values are taken to represent the social association of positive qualities and characteristics with things rather than relate to the realm of ethics and morals that guide human behavior, although it is understood that the values people hold also influence the values they assign to the physical world. The sum of the values perceived in a particular place or category of heritage coalesce to represent its cultural significance, typically summarized in a statement of significance, and it is this significance that a value-based approach ultimately seeks to conserve (see VALUE OR SIGNIFICANCE). The categories of heritage over which a value-based approach is applied have expanded considerably in recent decades to embrace, inter alia, museum collections, modern art, archaeological objects and sites, historic buildings and areas, and urban and rural landscapes. Thus this approach has become the dominant guiding framework in identification, documentation, interpretation, and various other facets of the decision-making process over heritage in the early twenty-first century.

The attribution of values to the material remains of the past existed well before a value-based approach assumed center stage in heritage management. Indeed, Alois Riegl, a professor of art history at the University of Vienna and general conservator in the Austrian state, articulated what is widely acknowledged as the first typology of heritage values in his 1903 pamphlet *The Modern Cult of Monuments: Its Character and Origin*. In this essay, Riegl sought to classify the constituent values associated with the concept of the monument (broadly defined) by subdividing them into what he termed “present-day values,” such as use and newness,

and “past values,” for example commemorative, historical, and age values. His conceptual insights were intended for practical application in the elaboration of a national system for conservation. Moreover, Riegl anticipated several critical concerns that would later occupy the international conservation movement, recognizing the multiplicity of values potentially associated with heritage and partially illuminating the contradictions and conflict inherent in adopting such an approach. For instance, a structured opposition exists between present-day and past values, age value ultimately depending on a contrast with the new and the modern. However, notable silences are also apparent in Riegl’s scheme, particularly concerning the role of the public in attributing values and the interplay between expert and lay knowledge. These, too, would come to greater prominence in the late twentieth century.

The most significant contemporaneous influence on the emergence of a value-based approach is the Australian Committee of the International Council on Monuments and Sites’ (ICOMOS) Charter for Places of Cultural Significance (the Burra Charter). The charter was first published in 1979 with the intention of providing guidance and establishing standards of practice for those responsible for places of cultural significance in Australia, and was subsequently reissued under various iterations up to the most recent version in 2013. In particular, it defined and popularized the term “cultural significance” as designating the combined aesthetic, historical, scientific, and social values of a place, although significance evidently has a longer genealogy of usage in the United States (Samuels 2008). A key motivational influence behind the creation of this charter was the perceived inappropriateness of applying western (particularly European) approaches to heritage management, as exemplified by the influential 1964 International Charter for the Conservation and Restoration of Monuments and Sites (the Venice Charter), to Aboriginal, indigenous, and nonwestern contexts (see HERITAGE: NONWESTERN UNDERSTANDINGS). In short, the central assertion of the intrinsic qualities of

material fabric is problematic when considering places of significance for cultures that may not produce monumental buildings and where oral traditions, knowledge, and social practices are more reflective of an intangible cultural heritage. By implication, new mechanisms were required to broaden the range of stakeholders and values involved in the conservation and management of such places.

Further impetus toward the adoption of a value-based approach came from the Los Angeles-based Getty Conservation Institute, whose research and advocacy from the 1990s stimulated the worldwide export of the principles emanating from the Burra Charter. The work of the Getty Institute manifested itself in a series of reports exploring the role of heritage values and conservation in a rapidly changing world. A primary focus was on elaborating methodologies for assessing cultural significance and for disseminating learning with partner organizations from the practical application of the approach to geographically diverse contexts and to different categories of heritage (see, e.g., de la Torre 2005). The rhetoric of high-level international discussions and their published proceedings increasingly revolved around more pluralistic interpretations of heritage and critical concepts such as authenticity, best exemplified by ICOMOS's influential 1994 Nara Document on Authenticity. By the start of the new millennium, values and cultural significance were in the foreground of conservation charters and conventions, most particularly the Council of Europe's 2005 Framework Convention on the Value of Cultural Heritage for Society (the Faro Convention), which essentially places people and human values rather than material fabric at the center of cultural heritage (see FARO CONVENTION). In parallel, and in response to these developments, the policies and practices of many national conservation agencies around the world were also changing to reflect the growing emphasis on values, significance, and public participation.

The integration of a value-based approach into the thinking of heritage agencies stems from the premise that this kind of approach results in better decisions and outcomes for heritage, predicated on the notion that understanding why something is important, how, and for whom is a necessary first step in effective

conservation. For proponents, the approach is asserted to facilitate a more democratic and comprehensive attitude to heritage management, given its emergence from a recognition of the multiplicity of ways—including contradictory and contested ones—in which different people and groups value heritage differently over time. Values and meanings are explicit rather than implicit. Thus a value-based approach has the capacity to improve participation by opening up conservation processes to greater scrutiny and public accountability, while also encouraging the continuous engagement of heritage professionals in self-reflective practice. Further ascribed benefits concern its flexibility of application, at various spatial scales (ranging from an individual object to a landscape) and to diverse aspects of the management process, from the identification of something as heritage to its conservation, use, and interpretation. Finally, the language of values and significance arguably provides a unifying framework that binds disparate heritage disciplines, practices, and communities of interest around the world via common reference points.

Value typologies are a key device in the application of a value-based approach; they consist of simple lists of values commonly associated with heritage and used in formal designatory processes and assessments of significance for conservation management plans. As this approach has gained greater currency in recent decades, the number of published typologies has proliferated, emanating from international and national heritage agencies, professional institutes, heritage practitioners, and academia. Widely cited typologies include those by Australia ICOMOS (1979), Lipe (1984), Feilden (2003), and English Heritage (2008; for a tabulated overview of value typologies, see Fredheim and Khalaf 2016). The expanded range of values that certain later typologies contain reflects the emergence of contemporary socioeconomic value sets designed to supplement those traditionally attributed to heritage, such as historical and aesthetic interest. Furthermore, nuances are evident in the multivariate ways in which the same or similar values are expressed; these differ according to the professional or disciplinary backgrounds of the author, the categories of heritage predominantly operated with, and the geographic focus of the elaborated typology. Typologies are criticized for their reductionist

potential, sometimes static nature, and inability to capture the full range of values attributed to heritage. On the other hand, they also provide flexible frameworks that can assist in a range of heritage management processes.

However, the worldwide expansion of a value-based approach and its encompassing of a broader range of heritage categories have not proceeded without critical reflection. Indeed, its emergence was in part a response to debates over whose heritage is being conserved, by whom, and for what purposes; and this approach, too, continues to be problematized within enquiries that critically examine the universal applicability of heritage values, practices, and ethics. For example, at the global scale, the sustained criticisms over the substantial imbalance of the sites inscribed on the World Heritage List by UNESCO as representing a monumental and tangible European heritage is illustrative of these debates. Additional philosophical and practical issues are apparent in the implementation of a value-based approach, not least the slippery concept of value itself. Whereas the dominant interpretation of heritage values in the humanities and social sciences is that they are mutable social constructs attributed by people, the belief in the intrinsic value of material fabric lingers for many in practice. This goes some way to explaining the apparent gap behind the rhetoric of a value-based approach and its variable implementation on the ground.

Several intersecting tensions underline some of the ongoing implementation challenges. First, the integration of economic considerations into value-based assessments is problematic. Fundamentally, this may be construed by some as demeaning of the “pricelessness” and intrinsic worth of heritage (Mason 2008). Although the concept of value is central to economics and cultural values, economic thinking typically reduces things to a quantifiable price determined by the market, whereas cultural values are plural in their construction, representing multiple meanings attributed by different groups and individuals in visual, textual, and other non-numerical ways. Thus the weighting afforded to economic values in comparison with cultural values and how the two are integrated into balanced decision-making processes over heritage are critically important matters if economic values are not to marginalize other types of value. Potential clashes of value

are most prevalent in the area of urban heritage, where redevelopment pressures are usually greatest. However, the economic importance of the global tourism industry also shapes the ways in which archaeological and other sites are exploited for economic ends, the attraction of international tourists being frequently privileged over the needs of indigenous populations and heritage, as Samuels (2008) illustrates in the case of Tunisia (see *ARCHAEOLOGY AND TOURISM*). In the context of scarce financial resourcing and political pressure to justify conservation through the promotion of its instrumental benefits, economic values will remain center stage for heritage.

A second tension relates to the involvement of the public and the concept of social values, taken to represent collective attachments to place and the associated meanings or values important to a community or communities (Jones 2017). This constitutes a particularly important consideration, given the aspirations of a value-based approach toward greater inclusivity. That heritage remains a primary domain of the expert is a prominent contemporary critique, particularly as it contributes to the propagation of what Smith (2006) terms an authorized heritage discourse (AHD), whereby certain values and ways of working are privileged and sustained through professional knowledge (see *AUTHORIZED HERITAGE DISCOURSE*). By way of mitigation, the Burra Charter and national heritage agency guidelines in jurisdictions such as England seek to position social and communal values on the same theoretical plane as historical, aesthetic, and evidential value. However, their integration has proven more difficult to achieve in practice, and social and communal values are often underrepresented or marginalized within designation, management, and conservation processes for a complexity of reasons, including embedded institutional cultures and policy-maker concerns over their transient nature (Jones 2017). Achieving a more representative heritage and promoting its sustainable stewardship with the community may be difficult to bring about until such values are given due regard.

Several alternative approaches advocating a “living heritage” and a “narrative-based” conservation philosophy have been articulated by those who are critical of a value-based approach (Poulios 2010; Walter 2014). These

analyses share a fundamental concern with the philosophical underpinnings of a value-based approach, which is argued to remain rooted within a nineteenth-century western conservation paradigm, thereby ensuring a continued focus on the material authenticity of fabric and on the dominance of professional expertise. Such privileging of physical fabric, they argue, creates a sense of discontinuity between the past and the present-future, effectively rendering the material world static (Poulios 2010; Walter 2014). However, neither of these alternatives are sufficiently well developed to supplant a value-based approach, particularly in its application to a broad range of heritage categories, nor do they yet provide a realistic means for day-to-day heritage management and decision making. Indeed, a living heritage approach applies largely to living heritage sites, loosely defined as those that maintain their original function, traditional mechanisms, and practices of ownership and management, as well as the continued presence of their sites' historical community (Poulios 2010). Consequently, examples include those sites that retain a religious function or where customary laws, traditional practices, and myths continue to operate. The question of authority over conservation decision making also persists with these alternative approaches. Nonetheless, they raise pertinent questions, not least by exposing universalizing tendencies while pointing toward the application of a pragmatic, situated ethics approach to the differing circumstances of diverse forms of heritage.

Other critiques seek to strengthen the conceptual foundations of a value-based approach and to improve aspects of its practical application. For example, Fredheim and Khalaf (2016) propose a typological framework for "holistic" value-based approaches that involve a three-stage assessment of significance, which consists of the identification of features of significance (what the heritage in question is), aspects of value (why it is valuable) and qualifiers of value (how valuable it is). The first stage is concerned with both tangible and intangibles attributes, while the third is where issues of value conflicts and prioritization are most likely to play out. Importantly, Fredheim and Khalaf recognize the mutability of values and the intergenerational changes that may inevitably occur in how people value the same thing over

time. This not only implies the necessity for periodic or cyclical reviews of significance, but also raises for future generations the vexed question of letting go of some aspects of the present heritage in light of changing values and new conservation challenges such as those presented by climate change. After all, destruction is also a judgment of value, and using the language of values and significance to determine a way of expressing the attribution of nonpositive value is, arguably, a necessary task (McClelland et al. 2013). Although aversion to the loss of heritage is a central organizing impulse for the conservation movement, such traditional orthodoxies are undergoing challenge in theory and practice.

Valuable future directions in research theory and methodology concerning a value-based approach will conceivably focus on the application of new methods and approaches to improving public engagement with heritage. In particular, social research and ethnographic methods, such as focus groups, qualitative interviews, participant observation, and oral histories offer appropriate means of divining the social values attributed by communities, while taking into account the fluid process of valuing heritage (Jones 2017). The use of digital technologies and tools will also likely be important in this regard, offering new ways for the public to interact with heritage and to capture, visualize, and integrate the multiple aspects under which it is valued. Furthermore, these new methods and approaches will potentially intersect with community-led, collaborative, and coproduction initiatives, involving, but not necessarily being controlled by, heritage professionals and agencies. Of course, realizing such methodological strategies in practice will present many challenges, including the lack of knowledge of social research skills in heritage agencies and other resource deficiencies that may undermine the capacity to sustain ongoing and dynamic relationships with the public.

Heritage Business and Marketing

CHRISTOPHER D. DORE

Heritage Business International, L3C, USA

KENNETH AITCHISON

Landward Research Ltd, UK

Over roughly the last 40 years—one generation of professional practice—archaeological practice globally has become part of the private sector both in large and in small countries. The rate of privatization has varied by country, but the trajectory is clear: state- and benefactor-sponsored archaeological work through direct funding and grants (which dominated the nineteenth century and the first half of the twentieth) is a shrinking component of archaeology. Thus, while archaeologists continue to be driven altruistically by professional values such as preservation, research, and education, the ability to be successful in realizing these values now requires competency in business and marketing. Archaeological charities and nonprofits must be financially viable if they are to achieve their missions, and for-profit firms must return shareholder value. Any inability of heritage organizations to meet their business requirements jeopardizes their archaeological objectives.

Research into archaeology's private sector requires use of disparate and uneven data. Some parts of the world, such as the United Kingdom and the European Union, have robust data on private archaeological practice. In 2015 the United Kingdom had an industry size of approximately US\$218 million (Hook et al. 2016; Aitchison 2015). In North America, Canada currently has an archaeological market of approximately US\$66 million and the United States one of US\$921 million (Heritage Business International 2016). Mexico has no private sector and the government is the major provider of archaeological services. Were archaeology to be privatized in Mexico, it could have an annual size of approximately US\$67 million (Dore 2016).

Throughout South and Central America, contract archaeology is the norm, too. In 2013 the Society for American Archaeology's Committee on the Americas presented research that identified that, across 18 countries, 73 percent of professional archaeologists worked in contract archaeology, the remainder working in academia. By contrast, the well-developed sector of applied archaeology in Japan is typically delivered through not-for-profit associations linked to local municipalities (Okamura 2014).

In Europe, delivery of archaeological services by private companies has become the norm since 1990 in western and northwestern countries (Ireland, Spain, Portugal, the Netherlands), but elsewhere significant state-provided services continue to exist. In central and eastern European countries, private company activity is still regulated by centralized authorities such as academies of sciences. In France there is nominally a level of competition between companies and locally based not-for-profit organizations (*sociétés anonymes* and *collectivités territoriales*), but the overwhelming majority of archaeological compliance work is undertaken by the Institut National de Recherches Archéologiques Préventives, a nominally autonomous body under the control of the French government.

Comparing the overall size of the archaeological market with traditional research funding from government and private foundations illustrates the changes of the past decades. The total value of all grants for archaeological research at UK universities in 2014–15 was approximately US\$30 million (calculated from Technopolis 2017: 39), less than one seventh of the total value of the United Kingdom's private sector archaeological market. In Canada, traditional research grants have averaged about US\$1.5 million annually over the past 15 years, only about 2 percent of the total Canadian archaeological spending. In the United States the percentage is about the same: traditional research funding is approximately US\$25 million (Altschul and Patterson 2010), about 3 percent of the total US archaeological market.

Furthermore, while research funding in both Canada and the United States has remained roughly static, overall archaeological spending continues to grow. Figure 1 provides, as an example of the growth of the private sector, annual archaeological spending in the United States since 1971.

Heritage business is not limited to archaeology, although archaeology is the focus here. Six segments of the heritage industry have been defined. Archaeologists are primarily employed in the heritage compliance sector, but can be found across all sectors. This sector covers consulting work done by cultural resource management firms for environmental compliance. Multidisciplinary environmental and engineering firms perform significant portions of work in this sector and, in recent years, have been gaining market share from dedicated cultural resource firms. The heritage tourism sector offers travel and travel-related tourism to heritage resources, areas, and attractions. The heritage media sector consists of magazines, television, software, and books focused predominantly on heritage and heritage content. The heritage research, preservation, and education sector consists of organizations focused on conducting heritage research, student and professional training, and preservation activities; it

includes colleges and universities, repositories, and nonprofits focused on public education, preservation, and research. The heritage attractions sector deals with the management and operation of specific heritage attractions, for example museums. The heritage design and construction sector is made up of architectural, planning, and construction firms that specialize in the renovation, restoration, and preservation of heritage resources.

Funding for commercial archaeological work comes primarily from government or privately funded construction, extraction, or infrastructure projects as part of an environmental, heritage (see ASSESSMENT: HERITAGE IMPACT (HIA)), or social-impact assessment process. Thus money flows from the project sponsor to the archaeologist. Sometimes the funding is direct, but more often there is a chain of agencies or companies between the sponsor and the archaeologist. Typically, archaeological contracting is done in business-to-business (B2B) or government-to-business contractual relationships and falls into the general business category of professional services. While commercial archaeological contracting is generally a service, clients of archaeologists often think they are purchasing a product, because what is

delivered to them is a report—and this is also what they need to present to regulators in order to receive permits for their projects. Archaeologists often have very specialized skills and expertise in types of analyses and archaeological sciences (see *ARCHAEOLOGICAL SCIENCES*). These archaeologists may be found working for other archaeologists, providing their specialized services in B2B relationships.

Education

Many archaeologists believe that the heritage industry is unique and that this somehow means that general business principles therefore do not apply. In fact, archaeological consulting firms are almost identical to other professional services companies, and it is very difficult for the heritage industry to increase productivity levels, particularly in labor-intense compliance work. Some archaeological practitioners have formal business training and degrees, but most of them do not. Catering to the perception that heritage business is different, a few educational institutions are now offering business training expressly applied to the heritage industry. A few examples are Jiwaji University in India, which offers an MBA in heritage tourism management, Edinburgh Napier University in the United Kingdom, which offers an MSc in heritage and cultural tourism management, Simon Fraser University in Canada, which offers a professional master's degree in heritage resource management with 25 percent business content, Universitat de Barcelona, which offers a doctoral degree in the management of culture and heritage with business and economics content), and the American University of Rome, which offers an MA in sustainable cultural heritage with business and economics content. Additionally, some not-for-profit, low-profit, and for-profit organizations also offer business classes and programs that target working professionals in the heritage industry. Heritage Business International, L3C is an example of a low-profit firm that includes business education for heritage professionals in its mission.

There are also business trade organizations that specifically target archaeological and heritage consulting firms, mostly in the compliance

sector. Members of these organizations are firms, not individuals. In the United Kingdom, the Federation of Archaeological Managers and Employers provides business data and best practices for its members and advocates policy. In the United States, the American Cultural Resources Association performs similar business support and education functions for its members.

State of the industry

The private archaeology industry in the United States essentially began with the passing of the National Historic Preservation Act in 1966. At that time, most archaeologists were employed in academic institutions, museums, and federal government bodies (primarily the National Park Service). While the law was passed in 1966, regulations detailing the compliance process were published only in 1974, and it was only about a decade later, as the volume of work increased, that a wave of private firms were established to meet this new demand.

As shown in Figure 1, work increased dramatically in the United States until about 1991. Average annual growth (real dollars) from 1971 to 1991 was 18.9 percent. However, the combination of a recession in 1990–1 and market saturation led to a sudden decline in industry growth. Since 1991 average annual growth has been only 1.2 percent (Heritage Business International 2016); the US industry is sizeable at just under US\$1 billion (nominal dollars), but only small increases in value are now being realized.

In the late 1970s, a little capitalization and a lot of sweat equity was all you needed to establish a successful archaeological consulting firm. Today the market is significantly more sophisticated, firms are much larger, and a high level of expertise is needed across many technical and support functions to successfully compete in the marketplace for archaeological work. Few new firms are now being established, because a high level of capitalization is needed to be successful. While the industry meets many of the requirements for attracting capital, the critical factor of value return is lacking; and this makes it difficult to adequately capitalize start-ups.

In the United Kingdom, until the 1970s, archaeological fieldwork was undertaken by academics, museums, and interested hobbyists; there were no legal obligations for compliance work to be undertaken ahead of the destruction of archaeological sites, but a level of public pressure led to the establishment of organizations dedicated to undertaking unprogrammed salvage or rescue archaeology at that time. These were not-for-profit charities established on a regional basis and funded from central government grants.

The introduction of environmental impact regulations, together with the simultaneous recognition that archaeology could be expensive, that neither national nor local government wanted to take financial responsibility for this, and that the cost could in principle be handled through the spatial planning system (a responsibility of local government), led to the publication, in 1990, of a key policy document: PPG 16 (Department of the Environment 1990). This document established the principle that, in case developers were (potentially) going to damage archaeological sites, (a) they were financially responsible for mitigating this damage, for instance by financing fieldwork; and (b) they were free to select suppliers of their own choice to do that fieldwork. PPG 16 transformed UK archaeology and led to the rapid emergence and expansion of a market for archaeological services funded mainly by private clients.

In both the United Kingdom and the United States, the original founders of the firms established in the late 1970s and early 1980s are now retiring. Most of these firms were started with sweat equity, but have acquired significant value. They must now be purchased, and their sale price reflects this value increase. Many archaeologists with a professional interest in acquiring companies cannot afford to do so owing to their historically low salaries by comparison to those of comparably trained scientists. Nonarchaeologists who may have sufficient funds for a purchase generally have little interest in acquiring an archaeological firm, do not understand the industry and how it operates, and do not see the potential for an adequate return on investment. Thus, while a buyers' market currently exists for archaeological firms, many firms for sale

are having an extremely difficult time finding a buyer.

Two business trends have characterized the industry over the past two decades (roughly, since the start of the millennium). First, there has been a shift in perspective on the part of archaeological clients. Contracted archaeological work used to be considered value-added professional services work, much like the work of other highly trained professionals, and a market premium existed for education and experience. Today, however, archaeological compliance services have changed into commodity services (commodities are things where brand doesn't matter). They have become commodities because, in a typical client's mind, all firms in the market can do an equally good job of meeting regulatory technical requirements. There are quality differences, but there is no market premium on these differences. With commodities, price converges on cost, and margins are very small. To achieve business success, commodity firms must increase their margins more than their competitors, through hyperefficient operations, and must have a very large market share. Archaeological firms have neither large market shares nor high levels of efficiency; nor do they desire to change their business model from a value-added services mode to a commodities mode. This is one reason why the industry's value growth has been so low since the 1990s.

As in the United States, archaeological practice in the United Kingdom is a commodity service supplied by organizations that want to present themselves as professional service providers—and often by organizations that want to present themselves as providing a public good. Almost all the charities that started undertaking archaeological fieldwork in the early 1970s still have significant places in the market, and their legally constrained not-for-profit model contributes greatly to the extremely low levels of margins across the sector.

Historically, until the global economic downturn that began in 2008, UK archaeological practice was also hamstrung by high barriers to exit: many organizations that were competing in the market were artificially sustained by larger parent bodies, such as universities and city and county councils, which skewed the competitive process in their favor. Very few of these survived the intense

effects that the economic changes of 2008 had on the construction industry.

The second trend is that of market share. While the nominal dollars of the US archaeology industry are increasing, firms that are archaeological-only or heritage-only firms appear to be losing market share to multidisciplinary environmental consulting firms and engineering companies. In 2011, more than twice the number of archaeologists were hired by nonheritage firms. Additionally, the marketplace is very fragmented. The largest archaeology and heritage-only firms only have about 1.5 percent market share. This drops off very quickly, too, as there are only few large firms and many small ones. Growth through increasing market share is desirable because it drives purchasing power, optimizes efficiency and cross-functional excellence, and is a fundamental way of increasing value. Greater market share also has scientific advantages and allows for a larger influence over scientific standards, increased scientific expertise, and the ability to increase capabilities and scientific services.

Marketing

Marketing archaeological services is not different from marketing any other kind of service. Having an understanding of the distinctive aspects of the industry may influence marketing strategy and tactics, but there isn't anything inherently unique to archaeological marketing. Marketing is based upon a fundamental premise that not all work is equal in value. This means that some work (e.g., jobs, clients, sectors, types of work) will, for the same amount of cost, produce higher returns. Marketing is the process of always increasing the amount of higher-value work that a firm does.

Successful marketing requires a deep understanding of archaeological clients and their needs. This understanding can be achieved at different scales of breadth and depth—and these are inversely related. Surveys of clients and potential clients can provide a large amount of data very quickly and inexpensively, but standardized surveys tend to provide the “what,” not the “why.” Focus groups provide a better balance between data quantity and quality and allow for unstructured answers, probing, and discussion.

Interviews with individual clients provide the most insightful information, but these data may not be representative and are costly to acquire in meaningful numbers.

When the needs of prospective customers have been defined, these prospects are classified into market segments, which can be ranked for value. These segments may align with client industries such as transportation, mining, energy, and so on occasion, but many client industries can be grouped into a smaller number of segments. The segments then become the relevant units for marketing activities.

The next step is “differentiation”—that is, figuring out how one's organization is different from competitors with regard to the things your sectors care about. When firms and their products or services are the same, at least in the eyes of the consumer, a commodity market exists. So, to gain more value, firms strive to differentiate themselves from one another. This differentiation, though, should produce results that are as unique as possible to each firm and that should be difficult for competitors to emulate. Most importantly, differences must relate to the things that clients care about when selecting one firm over another.

Differences, by themselves, are not the end product. Many firms offering archaeological services list all the things they do on their websites or in their advertising collateral. Most clients do not understand why these things are relevant to what they need. To contribute to the marketing effort, the differentiators need to be turned into client benefit statements. How do the firm's differences benefit the clients in a particular sector? As an example, cloud-hosted project databases across offices may be an important differentiator but, for the client, the benefit is that they can check the status of their projects instantly from any mobile device. The benefits are the things that need to be articulated and highlighted; the way they are achieved—the differentiators—is secondary. Advertising these client benefit statements follows, with the intent of attracting new clients. Of course, the benefits must be delivered if the client is to be retained beyond the first job.

Heritage Ethics

TRACY IRELAND

University of Canberra, Australia

Heritage ethics concerns both the codes and principles that frame accepted practices in the field of heritage and much broader debates and philosophical concerns around the legal, moral, and social justice implications of heritage. The rise of heritage during the twentieth century as a complex cultural and political field and its formalization and institutionalization in national and international legislation and in other forms of governance has significantly impacted understandings of archaeology as a discipline and of the “archaeological record” as an objective entity, as the study of heritage reveals that cultural values are relative and contingent. These shifts have also helped shed light on how archaeology has been shaped within particular geopolitical and historical circumstances that have influenced both its practice and theory and its interpretations and findings. At the same time, archaeological epistemologies and practices, their focus on the material, and the research potential of the material as trace and evidence, have strongly influenced modernist concepts of heritage, shaping notions of what heritage is and how it is defined in legal and public policy frameworks. Concepts of what heritage is or can be, including the related concept of “cultural property,” have also changed significantly over this period, and many see heritage as an ever-expanding field as interest in the intangible and the contemporary overturns the idea that heritage must be old and monumental.

Also critical for understanding heritage ethics in the context of this recent history is the building and continuing impact of the major historical and intellectual ruptures of the twentieth century and their social justice implications: the events of World War II and the Holocaust; critiques of colonialism and its basis in racism; post-modernism and its critiques of expertise and

of the knowledge–power nexus; the influence of feminism and the rise of environmentalism and of forms of participatory democracy; and, perhaps most importantly, the rise of indigenous and other human rights discourses and of diverse forms of activism by indigenous and First Nations peoples.

As heritage is increasingly seen around the globe as an industry and as a part of a cultural economy, albeit in distinctively different regional forms, archaeological work is more likely to be seen as belonging to this wider cultural sector, and thus archaeologists are employed in a range of different settings, for example in private sector businesses and practices, in government and nongovernment agencies and organizations, and in museums, other cultural institutions, and universities. Archaeological research may be a component of a broad range of heritage-related processes based on legislation and associated with urban, rural, and industrial development, such as cultural resource management, cultural heritage management, archaeological heritage management, commercial archaeology, public archaeology, heritage conservation/preservation, conservation science, asset management, land-use planning, cultural planning, environmental impact assessment, land rights determinations, and so on. This in turn has the effect of making archaeological research explicitly subject to bureaucratic and legislative definitions of its aims and purposes, as well as to standards of public fiscal and legal accountability. The discipline of archaeology and the way it is taught in universities has thus been influenced profoundly by the increase in the amount of archaeological work undertaken as part of these heritage-related processes. In the context of this recent history, ethical codes and debates have proliferated since the 1980s, responding not only to well-established understandings of “stewardship” or to the obligation to conserve and curate cultural material, but to these changing forms of accountability. It is now generally accepted that all archaeological research is encompassed within the broader field of heritage and is thus also embedded within these social, cultural, political,

DOI: 10.1002/9781119188230.saseas0294

and ethical contexts (Ireland and Schofield 2015).

Heritage and archaeological ethics have tended to be analyzed in terms of three main types of ethical responsibilities of practitioners: stewardship responsibilities for cultural materials; professional responsibilities to the discipline and to heritage as an expert field of practice; and, finally, responsibilities to “stakeholder” communities, often understood as “nonexpert” and external to the discipline (Zimmerman, Vitelli, and Hollowell-Zimmer 2003). Thus the codes of heritage ethics associated with professional heritage protection and advocacy organizations combine modernist ideas of stewardship, academic freedom, professionalism, and disciplinarity—which go back to the nineteenth century and earlier—with more “postmodern” concerns about rights to culture and identity, recognition, and representation. Recent developments in the management of heritage, however, tend to see a move away from understanding ethics primarily in terms of these three discrete categories and toward approaches that seek to address the ethical implications of all aspects of heritage, including its history, its theory, its accepted practices, its methods, its institutions, its products, and their consumption (Meskell and Pels 2005).

A number of key debates have dominated the field of heritage ethics, expanding out from questions concerned with “who owns the past” or who has rights over particular forms of heritage to broader investigations of how disciplines were founded and shaped, attempts to understand the influence of western ontologies, epistemologies, and embedded normative conceptions of gender, class, and race, as well as more philosophical discussions of the ethics of remembering and forgetting in the aftermath of World War II and in response to the revision of colonial and imperial histories. The dimensions of heritage ethics have thus been transformed by international geopolitics and paradigm shifts around the cultural contingency of knowledge claims. Particularly significant here have been Foucauldian interrogations of the entanglement of knowledge and power, Latourian critiques of science and modernity, feminist scholarship and critiques of androcentrism, and critiques of orientalism and of colonialism adduced

more broadly from the field of postcolonial scholarship.

Colonialism’s enduring impact as a cause of contemporary social and economic inequalities gives rise to ethical debates that are perhaps dominant in archaeological and heritage research. Central here has been the treatment of humans remains, sacred artifacts, and other cultural materials accumulated by western scholars, museums, and collectors and the demands of indigenous and other colonized communities for various forms of control, return, restitution, and repatriation (Scarre and Scarre 2006). While many museums around the world have active repatriation programs as well as ethical statements and guidelines concerning these issues, this colonial legacy continues to be contentious and without a standard ethical response. The repatriation debate can clash with strongly held commitments to cultural stewardship, which remains central to concepts of the “universal museum” and world heritage—modernist concepts that continue to retain powerful currency in the community, particularly in the face of the damage or destruction of prominent heritage places and monuments in armed conflicts (Stone 2011).

Research on legacy collections, and new research involving indigenous people’s cultural heritage, human remains, and descendant communities, continues to deal with the ongoing impact of colonialism and of forms of neocolonialism; and they do so in ethical questions such as what constitutes meaningful consultation, informed consent, community control, participation, and collaboration and, more fundamentally, how to empower, recognize, and respect indigenous knowledge systems, ontologies, and axiologies. Complicating this arena even further in ethical terms, recent developments in the study of ancient DNA stimulate great community interest in questions concerning the perception of continuity between ancient and modern populations of particular regions. Concepts of race and racial classification have been reinvigorated in the public domain, in contexts that range from personal (e.g., family history and genealogical research) to national (e.g., in the rise of white supremacist organizations).

A second dominant theme in heritage ethics concerns the so-called illicit trade in antiquities and “illegally” excavated archaeological material.

The illicit antiquities trade debate encompasses a huge diversity of local specificities—from “subsistence digging,” whereby impoverished communities exploit archaeological materials as a resource to exchange for cash, to organized crime that feeds a flourishing demand for rare collectables and to war or postconflict situations in which cultural materials are made vulnerable to theft through the breakdown of law and order. Underwater cultural heritage, largely shipwreck material, constitutes a particularly contentious area of this debate, as schisms arise between the archaeologists who work toward making the sale of recovered historic shipwreck material illegal and those who salvage or excavate underwater sites in order to produce material for sale, sometimes through well-known western auction houses. The ethical debates around the trade in antiquities also brings into play the ideological commitment to a free market economy as a driver of competing ethical standards around stewardship, the authority of archaeological expertise, and the role of the universal museum, particularly as new museums develop rapidly in areas such as Asia and the Middle East, with new collecting agendas and rationales.

Cultural tourism, and the “experience economy” more generally, provide a further arena where questions of heritage ethics are constantly invoked. Many of these debates are linked to concerns around the impacts of globalization and the interaction of global concepts of heritage (particularly world heritage, as defined by UNESCO) with local values and economics (Labadi and Long 2010). The 2003 UNESCO Convention for the Safeguarding of Intangible Cultural Heritage was seen as bringing a much needed balance to the Eurocentrism of the World Heritage List; however, it is also argued to have perpetuated the divide between perceptions of the monumentality of western heritage and the impermanence of nonwestern cultural traditions (Smith and Akagawa 2009). Also, archaeology has often been used to uncover evidence of crimes against humanity or to reveal traces of tragic events such as disasters, battles, or massacres. In some cases, this leads to what has been termed “dark heritage and tourism,” raising questions about who profits from such tourism and whether such sites educate and perform important memory work or exploit forms of voyeurism (Stone and Sharpley 2008).

Tourism’s consumption of heritage places, and the narratives provided by archaeological research, also raise ethical questions around the authenticity of the outcome of heritage processes of protection, restoration, and interpretation. Where cultural practices, traditions, and activities are also consumed, both the impact of this form of commodification on often minority ethnic or cultural groups and its propensity to embed colonialist concepts of traditional or primitive cultures as well as economic disparities between the affluent, often first-world consumer and local communities continue to be key drivers for much research and activism in this field.

Ethical concerns around authenticity were central to much twentieth-century debate and to the development of heritage as a movement. Their centrality resulted in the establishment of a series of charters that articulate shared principles and standards, the best known being the The Venice Charter of 1964 (the International Charter for the Conservation and Restoration of Monuments and Sites). The conservation and restoration of heritage buildings and objects gave rise to specialized subfields of heritage and conservation ethics. This arena continues to be strongly defined by the ethic of stewardship and concerned with the objectivity or subjectivity of conservation, restoration, and preservation decisions. However, debates in conservation have also moved toward greater focus on community interests and human rights. Concerns nonetheless persist around professionalism and around the development of the particular forms of expertise required to establish the authority of heritage experts and to secure public trust in the authenticity of the outcomes of the heritage process.

Concepts of authenticity and value remain central to all forms of heritage governance, and thus to all decisions about the conservation, listing, and protection of particular heritage places and things. Such governance regimes commonly restrict forms of access, interpretation, and use of places and things that are no longer seen as compatible with the values formally endorsed as most important. This frequently gives rise to ethical concerns about how heritage is used by states and by other powerful actors to control particular narratives about the past, and how these practices and narratives can create subtle forms of invisibility around alternative versions

of the past and other cultural identities. In fact some scholars have suggested the need to redefine heritage completely, because of the way in which the heritage system is focused on determining the special significance of things to particular groups, necessarily excluding groups that do not share these values (Schofield 2014). The ethical implications of heritage governance regimes that focus on categories of value such as beauty, rarity, and the aesthetics of the patina of age rather than on understanding people's attachment to places and things create an intransigent dilemma for heritage ethics in terms of social justice. The structures of heritage management and legislation are purposefully constructed so that heritage may be assessed and prioritized by judging which items are more necessary to a community's future.

Current approaches to heritage ethics tend to see all heritage as inherently entangled with politics and economics and, more broadly, with questions of human rights. Approaches have tended to move away from conceptualizing the ethical considerations of archaeological and heritage research as specifically defined questions that are referred to at key points in designing, undertaking, and evaluating heritage work, and toward adopting an iterative, reflective process of interrogating the impacts, benefits, and implications of all research and of analyzing the ethics embedded in all the levels of theory and practice, as well as in personal allegiances and belief systems. A hallmark of contemporary heritage ethics is that modernist concepts of stewardship and expertise continue to be strongly influential and used alongside postmodern or relativist concepts, particularly as they are strategically employed to value and engender respect for indigenous and First Nations knowledge systems and cultures. In areas dealing with conflict, peace building, and postconflict reconstruction, the task of embedding a normative and shared ethics in the work of heritage institutions such as museums or in the world heritage management system continues to be seen as crucial. Recent reviews of heritage ethics in postconflict contexts discuss the need for normative ethics to help build the bonds of "thick trust" in fractured societies—for instance by bolstering museums and cultural institutions as neutral, authoritative archives, which the broader society can trust not to take sides or cover up

uncomfortable aspects of cultural heritage. Other research is more concerned with deconstructing heritage's foundational concepts (such as those of stakeholders, conservation, stewardship, and authenticity) and with understanding the ethical implications of the often "blackboxed" nature of these ideas. While current research in heritage ethics takes a variety of approaches toward how formal ethical codes and charters perpetuate forms of disciplinary and expert privilege, all attempt to engender a better understanding of the ethico-political implications of heritage and of how it may contribute to a broader social agenda. In essence, heritage ethics aims to engender reflective approaches, which continuously question current practices and provide a critique of their social justice implications.

Emerging issues and future directions for heritage ethics concern how heritage and archaeological research might respond to pressing social and environmental problems and to their links to contemporary geopolitical events and conflicts—including climate change and sea-level rise, migration, refugees, and movements based on exclusive forms of citizenship. Recent theoretical trends, for example the "ontological turn," posthumanism, and multispecies ethics, appear to have the potential to impact significantly on heritage ethics, particularly in the area of indigenous heritage, its challenges to nature–culture dichotomies, and the approach to interspecies connectedness that is emerging as a strong feature of ethical debates about the Anthropocene; at the same time, forms of iconoclasm and extremist ideologies not only draw on narratives of inequality, past injustices, and deep cultural traditions but also target for destruction the material symbols of heritage—actions that inevitably appear to draw responses centered on the need to protect and restore the cultural heritage rather than on the far more difficult challenge of restoring peace and dialogue. Similarly, far more nuanced ethical arguments and guidelines need to be developed around research into cultural and biological concepts of race and the use of DNA in linking perceived cultural groups with regions, territories, and nations.

Finally, the capacities of digital technologies—their challenge to forms of expertise and their transformation of social participation—have already generated intense discussion in the

arena of heritage and archaeology. Questions concerning digital preservation, replication, interpretation, and visualization will continue to transform not only debates in heritage ethics, but understandings of what heritage is and of how and by whom it can be experienced. Developments in digital heritage are commonly represented as driven by threats to “real” heritage—through conflict, climate change, population pressure, disaster. The concept that humanity’s heritage is a rapidly dwindling and fragile resource appears to underpin many discussions of digital heritage ethics. On the other hand, these developments can also be seen as a continuation of the long-standing tradition of using techno-scientific practices in heritage and conservation, practices that have always created ethical tensions between the purposes of “heritage” and the diverse experiences and expectations of those communities that value it.

Heritage Interpretation

ALISON HEMS

Bath Spa University, UK

There has been something of a revolution in heritage interpretation over the last twenty or so years, although, like most revolutions, it remains partial and incomplete. This short entry is an attempt both to describe something of that process and to ask “where next?” for the theory and practice of this particular aspect of professional practice.

The entry draws on examples of professional practice in the United Kingdom, but it is also informed by experience elsewhere and by a clear understanding that heritage interpretation, as a set of skills and approaches, draws on multiple sources of ideas and inspiration, which are relevant in a wide range of contexts: social, economic, and geographical, and on the different forms that heritage takes from place to place and over time. The issues raised by these examples are broadly applicable: the balance between audience and story, how those stories might be best told, who does the telling. The underlying assumption is that we cannot separate these processes from the wider context in which they take place—the site *and* the society that has decided that they somehow matter. The politics of heritage interpretation are as much part of this process as the focus group that helps identify the key story, decisions about media, or the care taken to make sure that the new display is as accessible to as many people as possible. Deciding whether to create tactile labels, or an autism-friendly space as part of a new gallery, are as much political decisions as they are interpretive ones.

The survey in this entry covers the period from about 1997 to 2017. It thus starts with the election of the Labour government in the United Kingdom. The government made a number of interventions in the arts, heritage, and cultural policy. These were less radical than one may have supposed, but they did embody a shift of

emphasis. It was this government that renamed the Department for National Heritage, with all its supposedly backward looking, old-fashioned connotations, as the Department for Culture, Media, & Sport (DCMS).

A great deal has happened since then, but in terms of broad cultural policy, of which heritage forms a small part, there has been a remarkable consistency in assumptions over this 20-year period. *The Culture White Paper*, published in March 2016 by the Conservative Government led by David Cameron, embraced much of what was already familiar and much of what was already happening somewhere. The language was different, and the balance between public and private funding had changed, but some enduring sentiments were still there:

This white paper seeks to harness the nourishing effects of culture. It seeks to ignite the imaginations of young people, kindle ambition and opportunity and fuel the energy of communities. It seeks to spread the gifts of our arts, heritage and culture to more people, and communities across the country and abroad and free the creative genius that can make a better world for all. (Department for Culture, Media, & Sport and Vaizey 2016, 6)

The most obvious transformation has been a conscious and growing focus on the audience and, to a lesser extent, on the potential for wider public participation in “interpretation.” This can be seen in government policy between 1997 and 2010 and in the requirement that nationally funded organizations should broaden their appeal to nontraditional audiences. The introduction of free admission to the national museums in 2001 was part of the same line of thinking, though this was more successful at increasing the number of visits—far beyond expectations—than it was at changing the profile of museum visitors themselves. At the same time, the museum profession in particular began to develop a much stronger sense of the social role of its respective institutions, the contribution they might make to health and well-being, and, in some instances, the part that they could play on behalf of their

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0295

communities. Much of this is now commonplace across the sector as a whole.

Behind this focus on audiences was a much deeper set of impulses that link heritage practice on the one hand, and public engagement with it on the other, to the impact of social, demographic, and cultural shifts within the wider society. From the moment Stuart Hall asked “Whose heritage?,” as long ago as 1999, the sector has had to think more carefully about the stories it tells—or invites others to tell—about one heritage asset or another, as well as about what might constitute heritage in the first place. Its response to that challenge has included some extraordinarily innovative and exciting interpretive projects. Elsewhere the sector’s response has been to continue to do much the same thing as it has always done, but with better signage (Hall 1999–2000).

The availability of different media and new technology has enabled us to create new experiences or to experience a familiar place or object in a new way. Exhibition planning and design, the architectural impact of a new visitor center, or simply rethinking the direction from which the visitor approaches a site all relate to, influence, and are influenced by the practice of heritage interpretation.

Funding and the basis on which funding is offered or sought represents another set of influences and imperatives, allied to and reinforcing the political context in which we define, manage, and interpret heritage. Audience numbers and profiles are important here too. The continuing instrumentalism of much government policy on the arts, culture, and heritage means that funding relates to what heritage can *do* rather than to what it *is*. Heritage interpretation and heritage learning are both key elements in this.

The term “heritage interpretation” is perhaps used most often in the context of “heritage sites”—archaeological, historical, or natural sites, places, or buildings. Each of these poses specific challenges and offers discrete opportunities: making sense of a building that survives only in fragments, finding ways of making a historic interior stuffed with great paintings and precious porcelain welcoming to families, balancing the cultural and environmental value of a particular location.

Interpreters work in museums and galleries too; curators interpret their collections. Placing an object in a display case is a form of

interpretation, together with the label that accompanies it and the catalogue that elucidates its meaning and significance. In a UK context, the interpretive process was often reduced to a series of decisions about media, which may or may not have related to the needs of the audience: the label and the catalogue, panels and signs, audio tours and displays. In the United States, interpretation included people too: tour guides, costumed interpreters, living history. The latter are now well-established techniques in the United Kingdom, through innovative work by organizations such as Historic Royal Palaces and through the adoption of such approaches as a means of “bringing history to life.” Interpretation, in this context, is closely linked to audience development—finding ways of appealing to new audiences—and financial sustainability—income generation through events and through activities which could extend the length of a visit to a particular site. The current interest in the use of contemporary art to interpret historic places or collections crosses the same divide. The contemporary art installation can bring another audience to the historic house; it offers a way of challenging or subverting the conventions of the museums. It can be a huge commercial success.

There have been lots of attempts at defining heritage interpretation, from Tilden Freeman’s early reflections to more recent statements and pronouncements. The Heritage Lottery Fund (HLF), a key agent of change for UK heritage practice, offers us this:

Interpretation is not just about facts and figures, it is the way in which the interest, value, significance and meaning of heritage is communicated to people. It is a learning activity which communicates the stories and ideas behind the heritage and provokes the audience to think for themselves, coming to their own understanding about what its subject means to them. (Heritage Lottery Fund 2013, 3).

As the major UK funder of capital projects for museums, heritage sites, and the natural environment, it is unsurprising that the HLF connects good practice in interpretation with the delivery of its own objectives for the initiatives it funds, be they a small, community-based archival project,

a new gallery, or the refurbishment and redisplay of a major museum. Projects are supported where they demonstrate a high probability of enabling people to “learn about heritage” and have an enjoyable experience in so doing, and where the project has the potential to encourage “more and a wider range of people to engage with heritage” (<https://www.hlf.org.uk/interpretation-guidance>). The Fund’s consistent validation of the audience and of learning as a key outcome for all the projects it funds has contributed more than anything else to the shift from media to the relationship *between* audience and media, as the hallmark of good interpretive practice.

The Association of Heritage Interpretation (AHI), a UK-based network aimed mainly at heritage professionals, for example, echoes the idea of this connection between interpretation and the audience for whom it is intended—the extent to which it can *change* how it might think or feel about a site, a collection, or an event. In 2017, its website stated:

Interpretation is primarily a communication process that helps people make sense of, and understand more about, your site, collection or event. It can ... Bring meaning to your cultural or environmental resource, enhancing visitor appreciation and promoting better understanding ... Enhance the visitor experience, resulting in longer stays and repeat visits ... Enable communities to better understand their heritage, and to express their own ideas and feelings about their home area.

The Association then goes on to quote Tilden and his definition of interpretation as an “educational activity which aims to reveal meaning and relationships through the use of original objects, by first-hand experience, and by illustrative media” (Association of Heritage Interpretation, n.d.).

Freeman Tilden published *Interpreting Our Heritage* in 1957. It is customary, though faintly alarming, to begin with him in any analysis of heritage interpretation—customary, because he is so often credited with founding the “discipline,” and alarming because we are still citing his six principles 60 years after they first appeared. The “our” of the title also raises as many questions as the text seeks to answer. These six principles are widely available online, usually detached from

the book in which they were listed. After an early career in journalism, Tilden turned his attention to the National Parks Service in North America and began developing the ideas with which he is still so closely associated. He insisted on the relationship between interpretation and the audience, that interpretation was not just a matter of conveying information, and that its primary aim was provocation, not instruction. He summed up his approach thus, quoting an unnamed ranger in the Parks Service: “Through interpretation, understanding; through understanding, appreciation; through appreciation, protection” (Tilden, 1957, 38).

English Heritage reworked this formula in the first decade of this century for the sites it managed. It imagined a “virtuous circle” of “understanding that leads to valuing, and then to caring and enjoying” the physical heritage of the castle or ruined abbey. In this instance, the unifying theme became the “story of England,” a narrative thread that united the public presentation of a diverse portfolio of some 400 or so properties. Visitors to these properties were invited to “step into England’s story” through targeted investment in the conservation and interpretation of those places where significant moments in England’s history happened (visit [step into england’s story](http://stepintoengland.org), which is part of English Heritage’s Story of England website). Already underway under its previous chief executive, this process was accelerated in 2015, when English Heritage ceased to be an agency funded by central government: it was reformed with a one-off grant of £80 million, which supported its transformation into a self-sustaining, independent charity (English Heritage, n.d.).

In this, the new English Heritage bore a passing resemblance to the National Trust, a charity since 1895 and increasingly successful as a membership organization and manager of its own portfolio of historic houses, stretches of coastline, and breathtakingly beautiful landscapes. Its own approach to interpretation was also undergoing something of a transformation at the same time. Neatly avoiding the vexed idea of a story of England—as though there could be such a thing—its interpretive principles were drawn together under the injunction to remember that “everything speaks”: “Colour schemes, smells,

what's on the menu. The style of signage, leaflets, activities, passing conversations. The position of things, parking, paths, benches, even bins. Every detail adds up to tell a property's story" (National Trust 2013).

This is a familiar basis for interpretive planning, a multidisciplinary and multidimensional approach to bringing together audience, story, and media at the right place and in the correct combination. The visitor is there implicitly, following the signs, choosing something for lunch, reading the leaflets. There is a connection between each of these elements—they mark a point on a visit, from arrival to departure—and they might share a common visual identity and be congruent either with the property or with the National Trust brand.

But there was a bigger idea at play here, underpinning these helpful interventions and interesting observations: the idea of a "spirit of place," which "defines the very essence of a property ... the one thing we want every visitor to understand and take away with them" (NT, 2013). As with HLF, AHI, and Tilden so long ago, here was the key message, the story that the visitor was not supposed to miss. To its credit, the Trust acknowledged that there would be more than one story and that visitors, in any case, came to its properties for many different reasons. But there was still, just like in the story of England, "a strong governing idea," without which "individual layers of interpretation will be no more than a collection of facts and won't add up to anything whole" (National Trust 2013). This could have been taken directly from Tilden's fifth principle: "Interpretation should aim to present a whole rather than a part."

Spirit of place can be a useful organizing principle, from which everything else can follow. The risk is an innate conservatism, a wish to preserve something that is held to be self-evidently worth preserving and that is also usefully vague and intangible. But it does not necessarily mean an absence of change, or that the moment preserved has to remain the same indefinitely. In the case of Dunham Massey, for example, shortlisted for the Museum of the Year Award in 2015, that spirit was evoked by "temporarily stripping out the traditional treasures of the house ... [to uncover] greater treasures still." As part of the Trust's commemoration of the centenary of the outbreak of

World War I, the house was redressed in its role as a hospital for wounded soldiers brought back to Cheshire in the hope that they might recover from their injuries. This "uncompromising decision," in the citation of the judges for the award, "resulted in a wonderfully moving, enlightening and wholly fitting tribute to the kindness and courage of the house's former occupants" (Hems 2015). Elsewhere the Trust has worked hard to encourage visitors to participate in the process of defining the spirit of a particular place, and has encouraged them to see it in new and sometimes unexpected ways. Where the processes of conservation and restoration would once have been hidden away behind hoarding and dustsheets, or the property itself closed to the public, visitors are now invited to look more closely at the processes involved in keeping the roof on or cleaning each tiny fragment of stained glass window. This, too, is a form of heritage interpretation, far removed from the laminated room guide or "Do not touch" signs of many historic houses.

And yet the partial revolution remains. The other significant change in heritage practice over this same period has been a widening definition of what heritage is—the "Whose heritage?" question again—and the emergence of community-based, locally driven, informal projects to define and interpret it. In this context, heritage interpretation is not simply an aspect of professional practice, a discipline with a set of conventions and expectations associated with training, skills, and possible approaches, but an activity in which everyone can take part. As a participant in the process of interpreting heritage, the public can act as author and audience at one and the same time, researching and revealing a story that matters to its members. That this is a possibility—acknowledged, if less often realized—is the most important change in the practice of heritage interpretation over the past twenty years.

Heritage Management

TERESITA MAJEWSKI and JEFFREY H. ALTSCHUL

Statistical Research, Inc., USA

Cultural heritage management (CHM) involves those practices that identify and evaluate a community's cultural heritage resources and the programs that ensure their transmittal to the next generation. In the United States, where CHM is more commonly referred to as cultural resource management (see CULTURAL RESOURCES MANAGEMENT) (CRM), CHM operates within a system that includes government agency practitioners, private firms (mostly for profit, but some not for profit) that do much of the infield work of CHM, and the academic institutions that train the students who eventually become specialist practitioners. In other countries elements of the system may be underdeveloped, or may not even exist. For example, in some countries, CHM work is exclusively or almost exclusively carried out by the government, and the private CHM industry is underdeveloped or nonexistent. Some authors, such as Carman (2015), consider CHM to be synonymous with archaeological resource/heritage management; but in its broader application, globally, CHM deals with much more than archaeological resources under the aegis of "heritage."

For CHM practitioners, cultural heritage describes a community's assertion of rights to define who its members are and what they deem important. This heritage includes all aspects of social identity that are essential for community self-definition: places, norms, and beliefs—how members are to behave and what practices and knowledge must be passed on to future generations to ensure cultural viability. Heritage has both tangible (buildings, monuments, sites, landscapes) and intangible (social behaviors such as pilgrimage, rituals, feasts, dances, food ways) aspects. Any of these

aspects may be important in the history of a community, but they only become heritage when that community imbues them with meaning in relation to how they inform members as to how to live their lives and act toward others (Altschul 2018; see COMMUNITY HERITAGE). The Framework Convention on the Value of Cultural Heritage for Society (the Faro Convention (see FARO CONVENTION)) of 2005, which emphasizes tangible and intangible cultural heritage as valuable resources, acknowledges the diversity of these resources and stresses their significance for sustainable economic development (see HERITAGE AND SUSTAINABILITY). Following the Universal Declaration of Human Rights, the Faro Convention acknowledges that human rights include the right to cultural heritage. Cultural heritage is not a static entity but evolves as the community changes. The role of CHM experts is to work with all stakeholders in a project, from proponents and regulators to community members and other interested parties; they are not simply passive agents but critical actors in the process.

A nation's desire to preserve its heritage is almost always pitted against economic development, particularly natural resource exploitation, infrastructure improvements, and urban renewal, which in many cases results in impacting or destroying tangible heritage and in disrupting or leading to the loss of intangible heritage practices. CHM must be situated within social, political, and economic contexts, and is therefore not simply the application of laws, regulations, charters, or conventions. It must be adapted to the circumstances of a particular country, or even to a specific case. In industrial societies, regulatory frameworks exist that ostensibly balance cultural heritage and economic development. In developing countries, these frameworks either do not exist or, if they do, they are enforced inconsistently. The fact that numerous overlapping laws, regulations, conventions, and charters protecting different aspects of heritage exist should not be surprising, given the importance placed on heritage at the local, national, and international levels.

Primary approaches to CHM

There are two primary approaches to CHM as it is practiced globally today (Altschul 2018). The first is the social license approach, where the burden of identifying and treating heritage is placed on the project proponent, and the second is the national patrimony approach, where responsibility for heritage is vested in the government. These approaches are not mutually exclusive and most countries adopt elements of both, although one usually predominates.

Many countries place the responsibility of complying with cultural heritage laws and regulations on the project proponent. Underlying this approach is the proposition that the party responsible for causing potential damage to a community's cultural heritage should bear the costs of determining what part, if any, of that cultural heritage is threatened or at risk and then should pay for whatever mitigation the community and its authorities deem appropriate. Social license implies that a community's acceptance of a project is conditioned on the proponent's agreeing to specific requirements, some of which may refer to protecting and conserving cultural heritage. Underlying the license is the requirement to comply with all laws, regulations, conventions, charters, and safeguards placed on the project proponent by government agencies and funding institutions. Beyond these tangible requirements, the proponent needs to engage and gain the trust of heritage experts and stakeholders (see EXPERTS AND STAKEHOLDERS) for the life of a project, which, in the case of infrastructure or resource extraction projects, can last for years, or even for decades.

The social license approach has one major flaw, in that it is paid for by the project proponent. And, given that the motivations of project proponents are to complete their project, cultural heritage is almost always viewed as something to be done as quickly and cost-effectively as possible. Without a strong, consistently and effectively enforced system of regulations, it is generally left to the proponent to decide how much effort, if any, should be placed on identifying, evaluating, and treating heritage resources. Efforts in these areas are often minimal, because it runs counter to the developer's motivation to find things that

will impact the progress or outcome of his/her project. Unfortunately, on this approach, local and descendant communities are often left out or marginalized and have little opportunity to comment on the results of studies funded by the proponent, which often claim that few resources exist to be impacted. No one should be surprised that, when heritage resources are found during the project, conflicts arise.

Some countries view their heritage as national patrimony (see HERITAGE AND NATIONALISM), and thus centralize responsibility for all aspects of CHM with the government. These countries argue that their cultural heritage is too important to be treated as a commodity. Altschul (2018) explains that, in the national patrimony system, the government determines the proper balance between heritage conservation and economic development; defines the financial and human resources needed to maintain this balance; allocates the resources; performs the necessary CHM services; and determines whether the services were performed appropriately. A national patrimony system makes CHM a government monopoly. There is little incentive for government workers to meet a budget or schedule, and lack of accountability, corruption, political pressures on CHM professionals, and inadequate treatment of heritage resources are often common occurrences. On this approach, CHM becomes a top-down activity, which often leads to the creation of a national narrative at the expense of local and descendant community heritage (as in the social license approach, the opinions of these communities are not taken into consideration).

Regardless of whether a country's CHM system adopts a social license or a national patrimony approach, the success of its CHM framework depends on meeting four requirements (Altschul 2018). First, CHM has to be resourced both financially and with adequate numbers of sufficiently trained CHM practitioners. Second, local and descendant communities must be empowered to be part of the system and be integrated into it. Third, there are strong government regulations and oversight of CHM; and, fourth, there is independent verification of the processes and services by objective experts. In some developing and transitional countries, successfully meeting the four criteria requires establishing a new CHM

system. Major infrastructure projects may offer the perfect opportunity to develop a country's comprehensive cultural heritage program (see Gunchinsuren, Altschul, and Olsen 2011 for Mongolia and Stokin, Novšak, and Plestenjak 2008 for Slovenia).

Regulatory frameworks and heritage safeguards

Currently, one of the strongest systems of heritage law is in force in the United States, and the highest level of protection is afforded heritage resources found to be significant (or potentially significant) according to the criteria for listing in the country's list of heritage places (the National Register of Historic Places, established by the National Historic Preservation Act [NHPA] of 1966). Heritage protection is generally only reserved for resources impacted by federal undertakings, although some of the states and municipalities have laws that follow to a greater or lesser extent the federal law. These laws also have procedures for assessing and mitigating the impacts of projects on resources and for stakeholder involvement. There is some overlap between environmental and cultural resource legislation. At the federal level, heritage protection is centralized for resources on lands owned and managed by the government and on projects for which federal permits are required. Although the system established by the NHPA has generally worked well, a major flaw is that the focus is on resources with identifiable boundaries (e.g., archaeological sites, buildings, and structures), and not on less tangible aspects of heritage. Influenced by international approaches to managing heritage resources, other designation programs have developed that incorporate a more holistic notion of heritage values. These include a focus on landscapes, traditional cultural properties, scenic and historic byways, geographic regions, and National Heritage Areas (Morgan et al. 2010). Public acceptance of these designation programs is variable and quite susceptible to changing political climate.

Other industrialized nations, such as various countries in Europe and the United Kingdom and its Commonwealth Countries and former colonies, have provisions for heritage protections

(see Carman 2015, 28–50 for the development of current structures), but these are quite variable and range from centralized to decentralized administration.

In developing economies CHM is much less consistently regulated, although many countries, including those in the “developing” category, have become states parties to conventions that protect, promote, and conserve cultural heritage—conventions adopted under the auspices of the United Nations Educational, Scientific and Cultural Organization (UNESCO) (see Altschul 2018 for an expanded discussion of these conventions). In fact many of the oldest and most widely known archaeological sites, some of which have been designated world heritage sites (see WORLD HERITAGE SITES DESIGNATION), are located in underdeveloped or developing countries. The World Bank classifies 140 countries in the world as “developing economies” (<http://data.worldbank.org/about/country-and-lending-groups>, accessed November 26, 2017). For the fiscal year 2018, 31 countries were defined by the World Bank as having low-income economies, which in 2016 meant a gross national income (GNI) per capita of \$1,005 or less. Another 53 countries were declared lower-middle income economies (GNI per capita between \$1,006 and \$3,955), and the 56 countries eligible for World Bank funding were classified as upper-middle income economies (GNI per capita between \$3,956 and \$12,235). Most lower-income countries are in sub-Saharan Africa, the other two groups being dispersed throughout Africa, Asia, Latin America, and eastern Europe.

Altschul (2018) explains that all developing economies accept aid, grants, and loans from industrial countries and from multilateral financial institutions (MFI) that the industrial countries support. Underlying the concept of economic aid is the belief that, in exchange for allowing the growth and expansion of private enterprise and public infrastructure, the well-being of the people and society in that country will improve. Most of the inhabitants of the countries that receive aid are skeptical of this assumption and generally believe that the rich and powerful will reap the benefits of economic development, leaving the plight of the common person unchanged. Altschul characterizes this dilemma as a “Faustian bargain,” and

others concur that CHM as a top-down activity has the potential to re-create paternalistic, colonial structures, given that external assistance often delays or obviates the development of a sustainable heritage management system within the country that receives assistance (see Murimbika and Moyo 2008 for a case study from Zimbabwe).

On a more positive note, MFIs such as the World Bank and the International Finance Corporation, which fund projects in developing countries, have been building cultural heritage safeguards into their loan processes. Private financial institutions are following in their step by also committing to the Equator Principles (Altschul 2018). Some multinational companies have issued their own guides for integrating CHM into their projects (e.g., Rio Tinto 2011).

Best practices

Responsible CHM follows an adequately scoped and funded inventory of tangible (and intangible, as applicable) heritage resources, evaluation, and mitigation of impacts, which may include resource preservation or avoidance strategies (see *ASSESSMENT: HERITAGE IMPACT (HIA)*; also Carman 2015, 79–155) or, in the case of historic buildings and structures, repurposing and adaptive reuse. The value or significance (see *VALUE OR SIGNIFICANCE*) of each resource is evaluated, normally in relation to research questions that were outlined and integrated into project planning from the beginning. Successful projects will integrate community involvement (see *HERITAGE AND COMMUNITY ARCHAEOLOGY*), as well as appropriate planning for project reporting and for the management and curation of digital, archival, and excavated materials. Public outreach (see *PUBLIC ARCHAEOLOGY*) should be built into projects whenever possible. Standards of practice should ideally be similar enough to promote data sharing, digital preservation, and access, and the support of the conservation of archaeological resources. Ideally, they would reflect standards and practice in the modern developed world. As McManamon, Stout, and Barnes (2008, 19) note, the “liberal’s dilemma” in archaeology relates to “whether professional

activities should be conducted strictly according to western, scientific standards and guidelines or should be changed to incorporate culturally relevant modifications when practiced in traditional communities.”

Occasionally the qualifications for CHM professionals are outlined in legislation or regulations, but more often the standards for practice come from entities such as the Register of Professional Archaeologists and the Institute for Archaeology, and as part of the ethical principles of professional societies such as the Society for American Archaeology, the European Association of Archaeologists, and the American Cultural Resources Association, among others (see *ETHICS IN CONSERVATION*).

Challenges

One of the greatest challenges facing CHM today is how best to assist developing countries in finding an acceptable balance between preserving their heritage and economic growth. It is also an area of great potential for using cultural heritage to redress the social inequities of the past and to advance social well-being. What can be done to build sustainability in the CHM sector? A country’s heritage should be translated into local economic and social capital and should involve capacity building. Only when local communities retain the sense of ownership for their heritage can site protection and heritage management become sustainable (Murimbika and Moyo 2008).

An equally vexing challenge is how to address the global issue of the uneven nature of academic training for CHM professionals, even though some universities have specific degree or qualification programs dedicated to heritage training. Differences between academically based research and CHM are profound. Biehl (2013, 45) recommends that the graduate curriculum in archaeology (preferably in collaboration with sociocultural anthropology) be modernized and redesigned so as to meet the increasing demand of heritage managers trained within an international and interdisciplinary framework. Training should also be available to museum studies and museum management graduates, tourist industry

managers, law and policy makers, and other professionals whose work interfaces with CHM.

Heritage Planning and Design

KRISTER OLSSON

University of Gothenburg, Sweden

TIGRAN HAAS

Royal Institute of Technology, Sweden

Heritage planning and design is here understood as an amalgamation of, or the intersection between, urban heritage and urban planning and design. In the past few decades, drastic changes in urban economies have resulted in an urban planning and design increasingly directed toward the reinvention of place. In particular, this has affected places that have been exposed to severe structural change. In the various urban planning and design ideals that have emerged as a response to societal development, the past plays different—direct or indirect—roles for future urban development. In many cases the past—for example, in the form of historical sites—is considered a resource for development, for example in place branding and marketing strategies. In other cases the past is seen as an obstacle to urban development or as having no value for it. Heritage planning and design also means an approach where projects are developed in harmony with the community and with all its inhabitants. Heritage-based planning and (urban) design can be seen as an approach to community development that sets a foundation for building and nurturing a unique, authentic, and place-based community identity and contributes to a sustainable economic base. This urban planning and design principle demands respect for the cultural heritage of a place and a balance with tradition.

Urban planning and design is a composite concept, and thus not straightforward in its meaning. Urban design can be described as architecture on a larger scale and within a broader context, or as a bridge between architectural design and urban planning. Urban planning is primarily concerned

with the welfare of the citizens; with water and land-use management, including transportation, housing, commercial and public services, communication networks, ecology, and many other urban issues. Planning can be distinguished as a process-oriented activity and design as a product-oriented activity. Hence urban planning and design is here understood as a cross-border field between the urban context, the planning process, and the design product. In this particular case, the urban context comprises the urban heritage.

Heritage and emerging processes of dealing with the past

The traditional view of heritage is that it consists of material remains from the past with historical values as defined by heritage experts. In urban heritage management, the common method has been identification and protection of monuments and well-defined areas on the basis of an authorized heritage discourse (AHD) (Smith 2006). Hence management has relied on expert values within academic fields traditionally concerned with cultural heritage, for example art history, architecture, and archaeology.

As expert values, these are assumed to correspond to values in society at large. Consequently, they are decided upon independently of the values held by other interests, which in general are based on completely different perspectives concerning the urban environment, for example perspectives held by urban planners and designers, real estate owners and developers, and, presumably, various groups of citizens. It is quite clear that in urban planning and design practice, in which concrete values of different kinds have to be weighed against one another, this assumed correlation between expert values and the values held by other interests is not at all axiomatic. Conflicts between various interests over how the urban environment should be managed are a common experience in practice. For a long time during the twentieth century, the development of the

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0297

conservation movement presupposed that there is a fixed quantity of heritage objects with intrinsic value to be discovered by heritage experts. However, in the past few decades this view has been challenged, and it has increasingly been acknowledged that heritage and its values are produced and defined, and hence are a construct in contemporary society.

The evolution of approaches to the past during the twentieth century has, according to Ashworth (2011), resulted in three different approaches, which from the 1980s coexist in what Ashworth calls an incomplete paradigm shift: the *preservation paradigm* (from the late nineteenth century onward), the *conservation paradigm* (from the 1960s), and the *heritage paradigm* (from the 1980s). In short, the preservation paradigm can be considered a traditional perspective on the past, where experts are concerned with the intrinsic values of specific objects for the purpose of safeguarding them from development or any other form of harm. From an urban planning and design perspective, the preserved objects appear as irrelevant or as obstacles to development.

With the conservation paradigm, the focus shifted to include ensembles of objects in addition to individual objects, to integrate contemporary use into the equation, and to involve policy makers beside experts. In a nutshell, contemporary use became an essential part of local development and of the revitalization of places. The heritage paradigm acknowledges, in contrast to the preservation paradigm, that value is created in contemporary society. Accordingly, the focus is directed toward the use of the past in the present; hence the users, rather than the experts and the policy makers, are at the center of attention. Furthermore, the heritage paradigm acknowledges that all places—and not only so-called historic cities—have a past with potential heritage values to be used in urban planning, design, and development.

Harrison (2013) has differentiated between *official heritage* (objects and areas authorized by public bodies and protected through legislation) and *unofficial heritage* (objects and areas recognized by individuals or communities but not publicly authorized and formally protected). Urban heritage is a complex system of the official and unofficial heritage, but also of more modest

objects and other built structures, which are spatially or socially linked to one another, as well as to the official and unofficial heritage. Accordingly, a certain monument, object or structure within the system is to a large degree characterized by the urban context—that is, by the spatial, social, cultural, and economic circumstances that distinguish every place and thus impact every object or structure in a positive or negative way. It is this interplay between different parts of the system that defines the urban landscape as heritage, rather than the specific monuments and areas that are identified according to the AHD.

The systems view on urban heritage, which is aligned to the heritage paradigm, defines it as a cultural infrastructure, comparable with other infrastructures as a frame for people's daily private and professional activities. By tradition, the concept of infrastructure is associated with technical systems, for example roads and railroads. However, these systems are not “infrastructure” just by themselves, but have the potential to function as infrastructures. In other words, the actual use (in a broad sense) is significant for defining a built (or other) structure as an infrastructure. Consequently, viewing urban heritage as an infrastructure underlines its potential role for urban social and economic development, that is, as a resource in people's everyday private and professional activities. Following this reasoning, in order to use urban heritage in urban development work, it is necessary to include a wider group of stakeholders in the valuation process. Hence the task is, in accordance with the heritage paradigm, to define the urban heritage as an infrastructure based on how people use and benefit from the urban environment rather than based on the preservation paradigm, in which historical values are ascribed to specific monuments and areas by heritage experts.

The urban environment results not only from deliberate urban planning and design measures, but is also a complex product of those measures and of emergent societal processes and general development. Hence, to a large degree, the urban product also derives from economic, social, cultural, and spatial processes of structural change, including economic and cultural globalization, deindustrialization, a diminishing public sector, increased mobility, and tough territorial competition. Consequently societal processes and

developments challenge contemporary heritage management and, in particular, traditional ways of working with heritage issues according to the preservation paradigm.

Moreover, to address large-scale structural change, a number of theories and ideals have directly or indirectly influenced the practice of urban planning and design. On one side, past urban planning and design ideals and practice are revisited and advocated as a solution to many contemporary social, economic, and environmental problems, where modern planning and design is believed to have failed. On the other side, any relation to the past is considered obsolete, and thus irrelevant to contemporary urban planning and design and to future urban development.

Urbanisms: contemporary ideals of urban planning and design and the past

The specific theories and ideals—urbanisms—that influences today's urban planning and design discourse have been examined in various ways by different scholars, often resulting in differing categorizations and definitions (Olsson and Haas 2013). In particular, a few ideals stand out as exceptionally relevant here: reurbanism, new urbanism, and posturbanism—as well as everyday urbanism. These various urbanisms are based on different notions about contemporary society and on future prospects and therefore represent different ideas about the role of the past in urban development.

Reurbanism could be described as being oriented toward constant urbanity; in particular, it addresses the repair of the urban fabric. In that sense, this particular ideal is oriented toward adaptation to the existing urban environments, restoration, and interpretation of the historical and contemporary form of the city. Typical reurbanism projects are carried out in urban areas that have lost their function, such as former industrial sites and harbor areas. In particular, the traditional European city, with its grid street plan, is modeled to complement the existing city. An example of an ongoing reurbanism project is Hagastaden (Haga City) in Stockholm, Sweden,

which is a redevelopment project around a former marshaling yard adjacent to the inner city. Often reurbanism projects are geared toward the idea that the city is a constant urban fabric with an existing building stock and a new one that produces density and stable forms throughout the space of the urban grid (this was evident throughout the World Trade Center Site New York Design Competition).

New urbanism is rooted in the late nineteenth-century and early twentieth-century social reformist town-planning initiatives. Likewise, it has a social agenda and is based on ideas of mixed use, a neighborhood concept, and an emphasis on public space. It is thus focused on the (re-)creation of the past as a dynamic reference for present and future urban planning and design. In particular, it can be noted that physical structures and complete town-making principles have more importance than single objects. New urbanism projects are in general directed at establishing new settlements in the form of small towns; typical examples are Seaside, Florida in the United States and Poundbury in England.

Posturbanism could be described as generic hybridity with a focus on reinvention and restructuring. Hence the past is irrelevant, except (maybe) for certain monuments that have primacy as works of art. Nevertheless, objects are more important than the urban structure. The built environment functions above all as a contextual backdrop; in short, emphasis is put on architectural monuments and iconic flagship buildings—"starchitecture"—that claim to be innovative and to express a new era. Examples of posturbanism projects are the Guggenheim Museum in Bilbao, Spain by Frank Gehry and Burj Khalifa in Dubai, United Arab Emirates by Adrian Smith at SOM—the tallest structure in the world in 2017 (approximately 830 m/2,722 ft.).

In everyday urbanism the city is not decoded solely in terms of physical form but rather in terms of lived experiences, in other words narratives and daily life are the means of transforming urban form. Everyday urbanism infuses a cultural preservation and place-making approach into the planning and urban design process by emphasizing the built environment, the

citizen input, local character and history, narratives, memories, and a sense and image of the place—its tangible and intangible elements and assets. It also opens the doors to economic incubation.

Thus, ideas about contemporary and future society and approaches to the past are expressed in different ways in different urban planning and design ideals. New urbanism, just like reurbanism, is based on ideals and qualities from the time before modernist planning and is trying to re-create them in contemporary urban planning and design. Thus both reurbanism and new urbanism acknowledge the past as an important model for future development, but not necessarily in a way that is rooted in the specific history of a place. Posturbanism, on the other hand, connects to an idea that the past has no real relevance for future development. In that sense, it could be said to align with the preservation paradigm, in that heritage objects are considered to be obstacles to development. Everyday urbanism on the other hand sees place-based community redevelopment as action, through ideas and solutions based on urban fabric, social kineticism, historic buildings, and infrastructure as well as on the history, customs, and culture of each unique place.

While globalization tends toward a certain commodification and homogeneity of heritage and culture, successful global cities still have a strong individual and particular cultural identity. The economic value of the culture of cities therefore lies not only in the arts taking place there but also in each city's urban and social fabric, its architecture, and its cultural heritage (Monclus and Guardia 2006).

Designing the past: cross-disciplinary understandings of heritage

Regardless of which ideal of urbanism dominates in urban planning and design practice and which paradigm guides most of the approach to the past, the resulting urban heritage affects people's urban experience. It also either stimulates or limits their everyday lives and provides opportunities or restrictions for business development. In the end, urban heritage is all about "designing the past."

In any given situation and context, the dominant ideal in urban planning and design, together with the prevailing approach to the past, will define the specific urban heritage and thus will influence how we understand the past.

Historic preservation theories and tools need to reflect the notion that heritage and culture (and urbanism) are ongoing processes, at once evolutionary and inventive, not static sets of practices and things. Heritage planning and design builds on an understanding that history and culture are valued resources through which we view the world and understand the place of our past, present, and future. We therefore need to understand the critical methodological tools that are necessary to a professional engaged in the investigation, interpretation, and evaluation of the urban built environment. Heritage planning and design demands cross-disciplinary studies and an understanding of heritage conservation and urban planning with a broad practical knowledge of the laws, regulations, and policies that apply to planning and conservation practice knowledge of urban design, public policy, and architectural and planning history and theory.

Moreover, two important aspects—branches of heritage planning and design—need to be recognized: *cultural urbanism* and *heritage urbanism*. Cultural urbanism refers to the distinctive social and cultural patterns that develop in cities, reflecting local culture and authenticity that encourages social interface (Meyer 2014). Heritage urbanism is essentially based on the principle that the heritage should not remain only a monument to the past (a protected work of art), but be also an active participant (a creative subject) in the contemporary life of cities.

The traditional ways of working in heritage management—mostly the preservation approach, but also conservation approaches that emphasize historical monuments and well-defined conservation areas from the perspective of heritage experts—imply that modest objects and the general urban landscape will be neglected and that a systems view on urban heritage will therefore not be acknowledged (curatorial preservation: closed and locked urban heritage). Urban heritage—with its physical and social qualities—is situated in a spatial continuum in which the interplay between different features and their relational meanings becomes an important value category in

contemporary urban planning and design aiming at urban development (urbanistic preservation: open systems urban heritage).

Heritage: Nonwestern Understandings

MOIRA SIMPSON

Evocative Art and Heritage, Australia

During the nineteenth and early twentieth centuries, the concept of heritage was largely associated with historicity, westernized aesthetic considerations, and the preservation of material heritage such as objects, buildings, monuments, and sites. From the middle of the twentieth century, nostalgia for the past led to the development of the heritage industry and the growth of public museums and heritage sites. From the 1970s onwards, civil rights activism and international efforts to establish universal principles for protecting cultural heritage turned the focus of dialogue about heritage upon the diversity of cultural and social practices and values and the various forms and functions of heritage in different cultural contexts. By the mid-1990s, however, it had become widely accepted that definitions of “cultural heritage” needed to be revised in order to reflect the diverse values and aspirations of different peoples. Heritage is now recognized as diverse and dynamic; and, while traditions and customs are a vital part of it, heritage is constantly being redefined and reshaped, and given new meanings and purposes.

In recent years, professionals in heritage-related disciplines such as archaeology, anthropology, historical interpretation, museum curation, and conservation have become more responsive to the concerns of other communities, whether indigenous, local, or source communities. Recognizing the rights of source communities as traditional custodians and decision makers, they have been engaging in dialogue, collaborative research, and community projects. These professions are also becoming more culturally diverse as more indigenous peoples and members of minority ethnic communities undertake university training and enter professional pathways into disciplines such as archaeology,

museum curation, and heritage management. As a result, the concept of heritage has been evolving and there has been a diversification of professional practices that better reflects the cultural values attached to heritage in its various forms.

World heritage

In the 1960s and 1970s, there was growing recognition of the fragility of the natural and cultural heritage and of the need for international action to initiate heritage protection strategies at national and international levels. Through its various agencies and programs, the United Nations was one of the key mechanisms for international discussions, providing opportunities for the participation of peoples from across the world. At the same time, civil rights campaigners, newly independent, formerly colonized nations, and indigenous peoples across the world were expressing their grievances on various issues such as self-determination, cultural heritage, lands rights, biodiversity, and intellectual property rights.

In 1970 UNESCO adopted the Convention on the Means of Prohibiting and Preventing the Illicit Import, Export and Transfer of Ownership of Cultural Property, which was designed to provide a mechanism for helping nations recover illicitly trafficked art and antiquities; and the UNESCO Convention Concerning the Protection of the World Cultural and Natural Heritage (the World Heritage Convention) was adopted in 1972.

Many local communities and indigenous people played a central role in discussions about cultural diversity and heritage, articulating their concerns and demands within the framework of human rights. Many value tradition and cultural heritage not just in terms of nostalgia or as an industry that can be exploited for economic development, but as an intrinsic component of efforts to sustain their own cultural practices and to maintain cultural distinctiveness in the face of globalization.

Indigenous writers and activists emphasized the religious and spiritual dimensions of culture

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

and highlighted the contemporary significance of “heritage” materials as part of living cultures. Intangible and spiritual aspects of culture were identified as part of the complex of characteristics that comprise culture. The efforts of indigenous peoples to regain rights to traditional lands and to halt further losses and the destruction of sacred sites were significant in illuminating the subjective nature of human responses to landscape and the continuing links between humans and the cultural and spiritual associations with the natural world. Initially the criteria for listing reflected the dominance of western perspectives on cultural heritage as historical and material manifestations in the forms of buildings, monuments, and sites.

With the increasing diversifications of values expressed in discussions, heritage was recognized as subjective—a cultural construct reflecting the diverse and localized meanings and values attached to places and objects. New criteria for the World Heritage List were adopted in 1992 to include cultural landscapes, a term that better reflects the true extent to which cultural heritage and natural landscapes are intertwined. The first cultural landscape to be inscribed was Tongariro National Park in New Zealand, in recognition of the cultural and religious significance of the mountains for the Maori people; it had previously been inscribed in recognition of their outstanding natural values. In 1994 the Uluru Kata-Tjuta National Park in Central Australia was inscribed as a living and associative cultural landscape of the traditional owners, the Anangu Aboriginal community. The World Heritage List now includes a greater diversity of cultural sites, with over 102 properties described as cultural landscapes.

Intangible and living cultural heritage

From the early 1990s onward, there was also growing awareness of the importance and fragility of intangible forms of cultural heritage such as language, literature, folklore, music, dance, theater, rituals, and ceremonies, which promote creativity and express identity. This movement further highlighted the biases of the prevailing ideas of heritage and became a central focus in discussions concerning the need for nations to

develop strategies and programs to protect and promote cultural diversity.

The first legal instrument to specifically address the protection of intangible cultural heritage was the Recommendation on the Safeguarding of Traditional Culture and Folklore (RSTCF), adopted by the UNESCO General Conference in November 1989. In 1998, the Executive Board of UNESCO launched the Programme of the Proclamation of Masterpieces of the Oral and Intangible Heritage of Humanity, emphasizing the importance of living, intangible heritage as part of world heritage. This parallels the 1972 Convention on World Cultural and Natural Heritage and its adaptation to include cultural landscapes.

The importance of cultural diversity and of intangible aspects of heritage has been reinforced in a number of other international statements, agreements, and programs. These include the Nara Declaration on Authenticity (1994), the revisions to the Burra Charter in 1999, the Tokyo Declaration on Cultural Diversity and Heritage (2000), the UNESCO Universal Declaration on Cultural Diversity (2001), the UNESCO Convention for the Safeguarding of the Intangible Cultural Heritage (2003), the UNESCO Convention on the Protection and Promotion of the Diversity of Cultural Expressions (2005), the Faro Convention on the Value of Cultural Heritage for Society (2005), the UN Declaration on the Rights of Indigenous Peoples (2007), and the Promotion and Protection of the Rights of Indigenous Peoples with Respect to Their Cultural Heritage, a study by the Expert Mechanism on the Rights of Indigenous Peoples (2015).

In the UNESCO Convention for the Safeguarding of the Intangible Cultural Heritage it is noted that intangible cultural heritage is sometimes referred to as “living cultural heritage” and that it is “transmitted from generation to generation, and is constantly recreated by communities and groups, in response to their environment, their interaction with nature, and their historical conditions of existence. It provides people with a sense of identity and continuity, and its safeguarding promotes, sustains, and develops cultural diversity and human creativity” (UNESCO 2003).

The concept of living cultural heritage emphasizes the creative and dynamic nature of culture

and heritage as continually adaptive and changing and highlights ongoing practices as primary mechanisms for preservation and cultural renewal. In many indigenous and traditional communities, elders are respected for the knowledge and skills they possess and are recognized as essential to the performance, transmission, and continuity of traditional knowledge and customs. The continuing practice of intangible cultural heritage can be a key mechanism for facilitating cultural renewal and for healing the effects of postcolonial trauma; in these circumstances cultural heritage is a necessary part of cultural survival in the present and in the future.

In Japan and Korea, key individuals whose practices and teachings were essential to preserving intangible forms of heritage were designated “living cultural treasures.” In 1993, the Republic of Korea proposed to the UNESCO Executive Board the establishment of a UNESCO Living Human Treasures program, which led to its launch in 1994. Member states are encouraged to implement systems for the official recognition of living human treasures whose knowledge and skills enable the performance and transmission of intangible heritage, and to develop strategies that encourage these individuals to further develop their knowledge and skills and transmit them to younger generations.

Heritage and human rights

As newly independent nations, indigenous peoples, and local communities became more active in discussions about cultural diversity, heritage, and human rights, they voiced their criticism of dominant western scientific research practices in fields such as archaeology and anthropology and called for western heritage professionals and institutions to recognize their rights to control, manage, and interpret their own heritage.

During the United Nations International Year for the World's Indigenous Peoples (1993) and the UN Decade of the World's Indigenous Peoples (1995–2004), a number of conferences were held in different parts of the world to address indigenous peoples' concerns about the environment, cultural and intellectual property rights, the exploitation of natural resources,

indigenous knowledge, and cultural heritage. An international conference organized by the Commission on Human Rights' Working Group on Indigenous Populations dealt specifically with the cultural and intellectual property rights of indigenous peoples. An outcome of the conference was the Mataatua Declaration, which called on states and national and international agencies to recognize indigenous peoples as the guardians of their customary knowledge with the rights to protect and control its dissemination. It also asserted the right of indigenous peoples to create new knowledge based on cultural traditions, emphasizing the dynamic nature of cultural heritage and its continuing link to peoples' present and future lives.

These sentiments were further emphasized by Indigenous Australian lawyer Terri Janke (1999) in *Our Culture, Our Future*, in which she identified 17 rights for which indigenous people were seeking recognition, reflecting concerns for protection and management of their cultural, religious and spiritual knowledge and materials. These include rights to define, manage, preserve, protect, and control indigenous cultural objects and indigenous ancestral remains, as well as natural resources and intangible forms of heritage.

The increasing importance that was placed on intangible heritage demanded changes to practices in disciplines and institutions that had previously operated within the western paradigm and that equated heritage with materiality and the past. This has seen a rise in community archaeology and history projects and greater collaboration between museums, local communities, and source communities—the cultural, ethnic, and religious communities from which artifacts originate.

Institutions such as museums—which have traditionally dealt with tangible heritage—have been challenged by the increased emphasis upon intangible heritage and by the emphasis that indigenous people have placed on the importance of intangible and spiritual aspects of heritage and in the continuing relevance of heritage to the lives of many communities. Their concerns highlighted the inadequacy of western notions of heritage and the differing values and multiple meanings that objects in museum collections

have for source communities, for the scientific community, for museums, and for governments.

In response, legislative changes and professional guidelines have been introduced in a number of countries to encourage museums to recognize the cultural heritage rights of communities, to work collaboratively with indigenous peoples, and to develop repatriation policies and practices. These documents encompass references to spiritual dimensions of heritage and reflect the diversification of the concept of heritage.

As museums and communities work more collaboratively, curators and conservators have learned more about the cultural and religious significance of the heritage materials for which they are responsible and have gained greater insights into the importance that some of the items in collecting institutions can play in maintaining and renewing cultural practices in the source communities.

Museum curators and conservators increasingly consult with religious practitioners in indigenous communities and major world faiths, to learn about cultural protocols and methods of care that should be used when working with sacred, ceremonial, or ritual objects. In some societies, sacred and ceremonial objects should be handled and conserved according to strict protocols, such as removal from display, specific methods of handling and storage, use or avoidance of certain conservation materials, or restricted, gender-specific access. Certain types of sacred objects are regarded as living beings that require particular forms of care such as feeding, the breathability of materials used for storing, or the practice of rituals that protect those handling them from powerful and potentially harmful forces. Some museums have been adopting culturally appropriate methods for storing, displaying, and conserving objects.

The 2005 Faro Declaration was explicit in stating that “knowledge and use of heritage form part of the citizen’s right to participate in cultural life as defined in the Universal Declaration of Human Rights” (Council of Europe 2005). This reinforces some claims for the repatriation of culturally significant materials, in particular funerary, religious, sacred, and ceremonial objects. However, the concept of world heritage value has been used by some directors of universal museums to argue

for the retention of important cultural materials and to resist repatriation claims.

Dissonant heritage

Heritage is acknowledged today as being diverse in nature and purpose, with multiple producers and forms. The democratization of heritage both reflects and facilitates the participation of different groups or “heritage communities,” which are defined in the Faro Declaration as those groups that “value specific aspects of cultural heritage and act to sustain and transmit it to future” (Council of Europe 2005, Article 4; Kisić 2013). Multivocality in heritage discourse facilitates the (re)interpretation of history by heritage communities, giving voice to those who were previously marginalized—minority ethnic groups, indigenous people, women, the LGBT community. The result is the creation of “dissonant heritage”: the presentation of historical narratives and multiple viewpoints that challenge conventional or dominant versions of history and deconstruct notions of a unified national or universal heritage.

In *Dissonant Heritage: The Management of the Past as a Resource in Conflict*, Tunbridge and Ashworth (1996, 20) contend that heritage is “a contemporary product shaped from history.” History itself comprises “selective attempts” to describe what has happened in the past, processes that legitimize some viewpoints while excluding others; therefore all heritage is, to a greater or lesser degree, dissonant. Tunbridge and Ashworth identify four of the most common contexts in which dissonance is active in the heritage sector (1996, 21–29). The first is a context where different sources present several conflicting culturally bound messages in the interpretation of “the same or related heritage.” As an example, one might consider scientific, Christian, and indigenous versions of human origins and the First People. The second context is one where alternative meanings are constructed by those receiving a message—meanings that are shaped by the recipients’ existing knowledge, beliefs, and values but are different and sometimes conflicting with the messages intended by the interpreter. Third, dissonance can be created when changing values occur within society or

within a cultural group, but the interpretation of heritage does not reflect those changes. This can result in presentations of heritage interpretation that reinforce dominant historical narratives rather than reflecting revisionist views of history; examples include the continuing interpretation of European colonial history in the Americas and Australia using terms such as “discovery,” “settlement,” and “battles” rather than acknowledging those events as “invasion,” “massacres,” and “genocide.” The fourth context is the interpretation of “difficult heritage”: aspects of history that are uncomfortable or painful, such as sites of trauma, atrocity, or war. The interpretation of sites such as the Nazi concentration camps in central and eastern Europe, the “Killing Fields” in Cambodia, and the slave-trade sites in West Africa are examples of difficult heritage, also referred to as dark tourism or thanatourism.

Heritage interpretation by previously marginalized groups or colonized peoples enables them to assert their identity and to resist dominant discourses. The presentation of multiple perspectives in heritage interpretation provides opportunities for dissonance and moves heritage from the cultural realm to the political. The promotion of diverse values and interpretations of historical events can result in conflict and hatred, but dissonance in heritage can also facilitate reconciliation and intercultural dialogue and contribute to cultural renewal. In *American Indian Ethnic Renewal*, political and cultural sociologist Joane Nagel notes that inquiry can then shift from “the search for ... historical vestiges of culture” to “study of the means by which native cultures have endured and adapted and continue to develop.” As Nagel notes, “the view of culture as action, rather than artifact, is an empowering depiction, one that transforms the image of American Indians from helpless casualties of the overwhelming forces of history to powerful players in their own survival and renewal” (Nagel 1997, 72). In this way heritage becomes a mechanism by which the hegemony of the colonizers can be challenged.

Memory

MILENA DRAGIĆEVIĆ ŠEŠIĆ

University of Arts in Belgrade, Serbia

Heritage and memory

Heritage as a form of memory directly linking the past (heritage and history) with present-day considerations, values, and expectations and is today widely recognized in many types of research, institutions, and communities. Society once used (controlled) history, archives, museums, and different forms of active remembrance (narratives, symbols, commemorations, monuments, memorials, and protected memory sites) to represent its past and identity. Today, memory work is part of not only public policies but also innumerable everyday citizen practices, creating complex interwoven relationships within family, neighborhood, community, interest groups, and organizations.

The recent growth of memory studies in research relates to shifts in many disciplines. The recounting of historical facts has been replaced by an understanding of the politics of remembrance and the interpretation of history within collective memory. Archive research has been complemented by extensive oral history focusing on personal memories and the emotions of common people. Political sciences have been put at the heart of nation-building by means of social (state, public) memorization and memorialization. Cultural studies have refocused their attention towards how the past is re-presented in popular narratives. Sociology and psychology, facing policy demands to understand social conflicts, trauma, and needs of reconciliation, have also developed approaches to memory production and transmission. Philosophy contributes reflections on memory, forgiveness, and reconciliation. Cultural resource management uses memorized intangible heritage as a key resource for development.

Cultural and other public policies have drawn attention to the politics of remembrance and oblivion because of the many dissonant issues raised within the politics of reconciliation after World War II, post- and neo-colonialism, and especially within UNESCO efforts to support cultural diversity and intercultural dialogue. Issues of memory and oblivion have been central to those debates due to controversies and discrepancies in interpretation of the past, especially linked to heritage with different meanings for different communities (so-called dividing or dissonant heritage).

UNESCO's Lists of World Heritage and World Heritage in Danger are important instruments for memory issues, especially the latter, "which focuses on heritage that is disappearing due to wars and armed conflicts, natural disasters, the consequences of industrialization or pure neglect" (especially when it comes to the "heritage of others," such as the heritage of communities that no longer live in a certain territory). Putting heritage on the list inscribes them in a collective memory of the world, raising interest in their preservation, understanding, and interpretation.

Cultural policies have been making a special contribution to the deepening of the heritage and memory issue by efforts to negotiate around dissonant heritage, asking museums, archives, and other heritage institutions to reconsider their permanent collections and open them to individual and collective memories that until recently have not had a place in them.

History of memory research

An implicit concept of group memory has existed since Greek times, but the history of memory research and memory studies begins in 1925 with Maurice Halbwachs' book *Les Cadres Sociaux de la Memoire* that introduced a concept of collective memory. In the 1980s Pierre Nora further developed memory studies by introducing the notion of *lieux de memoires*—material or immaterial symbolic elements of the memorial

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0370

heritage of any community. Reprinted in English in 1998, this work had enormous impact on many disciplines (historiography, archaeology, anthropology, and cultural studies) (Nora 1998).

In the 1990s several “memory schools” developed in Europe and North America. In Germany, Jan and Aleida Assmann reflected on the importance of cultural memory for nation building and the rise of nationalism, developing a body of work that developed important ideas such as distinctions between cultural, communicative, functional, stock, and intergenerational memories. Through numerous projects such as “The Past in the Present: Dimensions and Dynamics of Cultural Memory,” they have contributed to the development of memory studies and to a new culture of memory.

In the UK, Tony Bennett and other academics have revisited the notion and concept of museums as keepers of national past, using the term “memory machines” (Bennett 2004), while Paul Conner (1989) developed the concept of embodied memory by discussing how societies remember or forget, analyzing in its ceremonies socially negotiated practices expressed in manners, clothes, bodily gestures, and creation/use of place.

In the United States, scholars such as Andreas Huyssen are discussing “present pasts” and “amnesia”—how the past today is remembered or forgotten in media and politics, focusing especially on interpretation of visual expressions (Huyssen 2000). Marianne Hirsch meanwhile has introduced an important concept of “post-memory” (Hirsch 1997).

In Latin America and southeast Europe, interest in the culture of memory was linked to social traumas and memory transmission related to troubled pasts. Individuals and families connected by similar political persecution or war trauma (mass killings, “mass disappearances”) have nurtured transgenerational memory transmission as well as specific mutual contacts in order to fight government-supported social amnesia. That, together with explicit misuse of history and the manipulation of memory by governments (such as the project of antiquization in Macedonia called “Skopje 2014”), provoked scholars to approach issues related to the politics of memory and oblivion so as to demonstrate how far those policies inhibit social development, reconciliation, dialogue, and integration.

Paul Ricoeur (2009), for example, has questioned why certain historical events are memorialized as part of public policies everywhere (within the process of EU integrations all new democracies in Europe have built Holocaust museums), while other events of similar significance and extent are put into oblivion and not shared as contemporary cultural memory (e.g., the French war in Algeria). An important part of his work is devoted to oblivion and forgiveness, ethical considerations related to the truth of historical knowledge, commanded forgetting (amnesty), forgetting and manipulated memory, and forgiveness and forgetting as such—scrutinizing political strategies that deal with memory and reconciliation.

Memory policies

In the nineteenth century, implicit politics of memory and oblivion included heritage but were related more to ideology and politics (national identity) than to safeguarding heritage and memory for the sake of preserving cultural identity. The politics of remembrance and oblivion had been creating “appropriate” links between past and present within public space, but only through selective narratives that contributed to the sacralization of certain historical moments deemed suitable for ceremonies, celebrations, and commemorations (Assmann, Assmann, and Konrad 2010). These national processes of constituting collective consciousness and collective memory were done through three methods: *historization*, *aesthetization*, and *nationalization*. In *historization*, narratives idealized selected historical events and personalities (usually linked to independence, the creation of state, the Constitution). Within *aesthetization*, national cultural and artistic canons were created that reached every citizen through public education, thus contributing to a common cultural memory. *Nationalization* chooses only narratives, events, and visual representations that are thought crucial to the creation of national identity and character and that should be embedded in every individual and every subgroup of the nation. Although those processes and methods might seem spontaneous, they were politically led.

Paul Connerton identified seven types of forgetting: repressive erasure, prescriptive forgetting, forgetting as a necessity for a new identity, structural amnesia, as annulment, as planned obsolescence, and as humiliated silence. Two more reasons might be added: forgetting as a confused silence, and forgetting as a shameful silence. Different societies practice different types of oblivion. For totalitarian and authoritarian regimes, repressive erasure is a main strategy; in democratic societies, prescriptive forgetting is used if authorities believe it beneficial for all parties (e.g., a controversial event). Structural amnesia, very close to shameful or confused silence, occurs when there is a social consensus that some event (such as collaboration during occupation) is shameful or degrading for the picture that nation wants to build around itself. In those cases, monuments or other heritage artifacts are often forgotten, even if not destroyed or removed. Numerous statutes, for example, have in recent decades been removed from the public realm in Europe for ideological reasons, official memory policies seeing them as a danger to current political and social values. Sometimes they are put in new “sculpture parks” (e.g., Budapest, Druskininkai, Lithuania, or Moscow) but many are destroyed or sent to museum depots.

National public memory policies became a focus for academic research quite recently because of the use of heritage and memory in identity creation. Links have been clearly identified in many studies, showing ways of identity construction and representation from the mythologizing of historical persons and events (from Jeanne d’Arc in France to Abraham Lincoln in the United States) to the invention and misrepresentation of historical facts due to present political ambitions (e.g., conflicting interpretations of Alexander the Great in present-day Greece and the former Yugoslav Republic of Macedonia).

Globalization and migrations, on one side, and the creation of supranational communities such as the European Union (EU), on the other, demanded a new approach in reconsidering world history and world heritage as a common memory of the humanity. Retelling the past became a new policy demand of multicultural societies needing to generate a revised sense of a collective identity. Scandinavia, for example,

must integrate a Sami past into its memory, while all EU countries must deal with the shared troubled past that divided them throughout history; the role of heritage in conflict resolution has started to attract more interest (see *HERITAGE AND CONFLICT RESOLUTION*).

In some regions, such as the Mediterranean and South America, those initiatives do not have clear support from public bodies and relate mostly to the endeavors of independent groups and cultural communities that would like to bring their common standpoint to the memory of the world. The UNESCO program “Memory of the World” aims to list the documentary heritage of different countries that until now have been part only of national pride, and to highlight common heritage in regions that have not been widely known. For example, “American colonial music,” a documentary heritage submitted by Bolivia, Colombia, Mexico, and Peru, offers sixteenth- to eighteenth-century music from different countries of the American continent (as a testimony to the acculturation processes between indigenous, African, and European cultures). A similar example is the “Archive Middelburgsche Commercie Compagnie” submitted by the Netherlands, Curacao, and Surinam to enable better understanding of the slave trade in the eighteenth century. Such multilateral entries are still in a minority, however.

Bottom-up public memory creation

Civil society and artists have begun to connect their projects to bottom-up memory community movements. Accessible technologies open multiple possibilities for artists to actively relate to community heritage and memory. Video testimonies and oral history enable “heritage” to be broadened to include dialects, customs, and the artifacts of everyday life or of specific “overlooked” professions. Exhibitions such as “Armenians in Grenoble,” the life of miners in the Ruhr in Zollverein, or about contraceptive pills in the Hygiene Museum in Dresden were based on intangible heritage and artifacts collected together purely at the moment of the exhibition’s preparation because there were no pre-existing museum collections or custodians. In the United

States, Fred Wilson's exhibition "Mining the Museum" (1994) addressed historical injustices never seen in official heritage and memory spaces such as museums.

The artist Jochen Gerz uses participative methods to engage communities in searching forgotten issues linked to the negative past (i.e., German Nazism) and to create "counter-monuments," such as the "Monument against Racism" in Saarbrücken (Vickery and Manus 2016), the commemoration of 2,146 destroyed Jewish cemeteries on the *underside* of newly laid paving stones in a public square outside the provincial parliament now named "*Square of the Invisible Monument*." Such artistic projects in the long run contribute to a questioning of historical reinterpretation and returns forgotten issues to collective and cultural memory.

Local communities and groups linked in different ways are creating their own memory sites, monuments, or collections (real or virtual), wanting to contribute their individual memories and objects to the public realm, thus widening perspectives on official heritage and memory definitions. Often, they erect monuments in public spaces to directly transmit the message of a community fighting for forgotten values and claiming their right to offer their own interpretation of history. They became much more active in fighting for the status of local tangible and intangible heritage, finding inspiration and support in the new instruments of cultural policies such as the UNESCO World List of Intangible Heritage and the Council of Europe's Faro Convention (2005), but there are many other examples.

Planning and Tourism

HILARY DU CROS

University of New Brunswick, Canada

Introduction

By the early 1970s, considerable mistrust of tourism had built up, because of the negative impacts experienced by communities, thereby resulting in calls for more sustainable tourism. Sustainable tourism can be defined as tourism development that achieves an ongoing balance between economic benefits and social/environmental costs. The development of sustainable tourism has required effective and integrated planning processes to ensure that a host community and its cultural assets could absorb tourism and not allow it to dominate them. By integration in planning, people began to think of heritage, tourism, and conservation in one breath. With careful tourism planning, opportunities could be discovered and challenges could be faced.

Many different planning models have been devised over recent years to assist site managers in achieving sustainable tourism (e.g., Pedersen 2002; du Cros and McKercher 2015; Heritage Preservation 2016). They all share a number of features in common. In summary, the planning process involves the following ten steps:

- Background research and documentation
- A realistic assessment of the current situation, including an internal and external analysis
- Stakeholder consultation (undertaken at all stages)
- Specialist studies, as needed
- A realistic assessment of the site's potential to function as a tourism product and what measures are needed to achieve that potential
- Identification of options and the selection of the most feasible
- Establishment of a mission or vision

- Establishment of quantifiable and assessable goals and objectives
- Creation of specific action plans to achieve the goals and objectives
- Establishment of an evaluation and feedback mechanism to monitor achievement of the plans' objectives (du Cros and McKercher 2015).

Auditing tourism potential

The market appeal/robusticity matrix (du Cros 2001) is a proven assessment tool that can be applied in a proactive manner to assess tourism potential and identify management options prior to selecting a preferred site out of a number of options at a destination. It is predicated on the integration of different elements that constitute its two axes. The robusticity axis focuses on issues relating to cultural and physical values, while the market appeal axis reflects product and experiential values (see also du Cros and McKercher 2015). It can also be used to guide the planning process at the preferred site in order to identify fatal flaws and obvious impacts to be avoided.

The planning process

A planning process for sustainable tourism is usually best applied early in the transformation of an archaeological site into a tourist attraction. This is also the time when the process is most likely to be endorsed by all parties with a clear leader and a system agreed upon for them to work together. It is at this stage that some fundamental questions need to be resolved, such as:

- What kind of transformation of the site (sometimes also known as commodification) is appropriate to make its archaeological values more understandable to tourists, while being safe and pleasurable for them to visit?

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0464

- Also, what is the best way for the site to tell its story to tourists?

At this early stage, social and physical carrying capacity is of key interest. In particular, consideration of the total visitor numbers, visitor flows, and the impacts of seasonal or daily peaks in visitor numbers must be considered to prevent negative impacts from potential overuse for tourism (UNWTO 2004). Also, what role does the site play in the surrounding host community and what involvement will they expect in future tourism operations.

When sites have a clear financial orientation, the ability to generate sufficient income and an acceptable return on investment must also be considered. This step may involve presenting and evaluating a number of use scenarios for consideration. Typically, scenarios represent low, medium, and high use, or low, moderate, and high commodification. Commodification encompasses all the typical changes that are made to make a site understandable and physically accessible to visitors, including tourists. Each scenario is assessed against the likely positive and negative impacts.

Once consensus has been reached about the desired approach, then more detailed strategic marketing decisions need to be made about whether and how the site can stand out in a crowded tourism marketplace. Sustainable tourism is best achieved when specialists in marketing and those in management work closely together or through an approach that integrates both from the beginning. To understand how marketing actions could enhance management requires a marketing situation analysis.

Marketing and planning

Conducting such a situation analysis is a vital though sometimes neglected step in the planning process. In order to succeed, a tourism development project must show a clear understanding of the site's strengths, weaknesses, and limitations, the structure of its target market, and their expectations. Failure to acquire this fundamental knowledge heightens problems such as the risk of inefficient allocation of resources; over-

or underestimating the size of the market; and failing to manage the visitor experience (Chhabra 2009; Colbert 2013).

The situation analysis should be able to answer the following three questions:

1. What products do I choose to offer/not to offer?
2. What markets do I choose to target/not to target?
3. What competitors do I choose to compete with/avoid?

The first two questions force stakeholders to consider the core product to be offered and the core products not to be offered and to whom. As a general rule, the deeper the experience represented by the core product, the smaller the market, while the shallower the experience, the potentially broader the appeal of the site. The decisions made here will influence the next questions—defining which markets to pursue and which competitors to compete against or avoid. These decisions, in turn, will be influenced by the position of the site in the attractions hierarchy at a tourist destination: primary, secondary, or tertiary. Primary attractions are the must-sees; secondary ones often draw tourists who have already seen all the primary attractions, say on a previous trip; and tertiary attractions are of less appeal than the other two (du Cros and McKercher 2015).

While adopting a marketing approach means considering archaeological sites as products, it also means acknowledging that some types of visitors are more desirable than others. Indeed, managing demand is one of the key goals of marketing (Colbert 2013). Many of the adverse impacts noted in cultural tourism are a direct result of the failure to adopt a marketing management perspective, rather than the opposite. As a result of failure to identify clearly the core product, the target market, financial and nonfinancial objectives and a plan of action to achieve them, mixed messages can be sent to visitors.

One of the problems with integrating a marketing approach is access to expertise. Most providers of cultural tourism products are either small businesses or operate on a not-for-profit basis. They have limited staff, often tasked with

multiple challenges including marketing, and even more limited budgets. A second problem is that few archaeological attractions have formalized marketing plans to evaluate their position in the marketplace.

Goal setting and action plans

Finding a clear mission or vision for the site as a tourist attraction is necessary, before the rest of the planning process can proceed. The mission or vision must be compatible with the cultural values of the site. This is as important as deciding the core product, market, and message. This phase will require input from the previous ones, such as a value-based or use assessment, an audit of its tourism potential, and situation analysis.

The vision needs to be transformed into a set of goals. They must be SMART: specific, measurable, attainable, realistic, and timely. Goals are the benchmarks by which the success or failure of a cultural tourism product will be measured. Interim or milestone goals should also be identified. This will help site managers assess how well they are performing and how likely they are to achieve their targets.

Action plans can be developed, once goals are established, to ensure they can be achieved. Such plans may include conservation, excavation, or monitoring of sites during development; actions for presenting and interpreting a site; marketing responsibly; avoiding or mitigating negative impacts and continued consultation and involvement of key stakeholders. Care must be taken to ensure that these plans are integrated and compatible.

Tourism experiences

Sustainable tourism experiences resulting from well-designed interpretation can inspire tourists to perform behaviors that enhance the environment on site and at similar places at home. All tourism experiences are subjective and firmly related to several factors including knowledge, awareness, recollection, and feedback. They are also closely tied to the activities at an attraction and during on-site visits. Themed touring

routes that give archaeological sites some context have been given much attention in recent years, because they spread economic benefits more widely and can assist the tourist in understanding more of the broader history of a region.

Telling the story

Some archaeological sites have a more complicated message than others to convey to tourists who may not know much about their cultural context. In some instances, these places may be visually and historically complex, as in the case of the Roman Baths in Bath, England. Potentially a confusing site, it has been clearly labeled and the remains and their histories are carefully pointed out.

The tourism planning process needs to consider employing a variety of old and new techniques for information presentation, where funding allows, to bring a site to life. They include the provision of signage (locational, advisory, and interpretative); incorporation of new communication technologies and existing audio-visual ones; interactive and participatory activities (including voluntourism); and the role of human site presenters.

Audio-visual techniques of a modest nature are still viable options to convey messages and experience an attraction, such as audio-tours and quick response (QR) codes for mobile phones. Accordingly, there are also tourists who are happy to buy books and DVDs to take home afterwards to continue to study and experience the site. Hence it is still worth considering first whether older or simpler techniques of conveying information could be worthwhile in a particular situation, before launching into more complicated plans.

A new area of digital technology that has great potential to bring many complex and/or fragmentary archaeological sites to life is that associated with “immersive” or “immersive virtual environments” (IVEs). Often these projects integrate high-resolution digital datasets from archaeological sites (photography and 3D models) with immersive and interactive display systems (Kenderdine 2013). For instance, the *PLACE-Hampi* project was created especially

for the Kaladham Museum near the Vijayanagar World Heritage Site, Hampi, India. It features animation as part of the 3D immersive imagery. The animation (Indian mythological characters) superimposed on the 3D imagery is similar in effect to augmented reality efforts at other sites.

Meanwhile, other new nondigital interactive activities are being devised to distract tourists from overusing popular sites and channel their energies elsewhere. One such project is a visit to the physical replica of Tutankhamun's tomb that has been made possible by using high-resolution recording and is a part of a key initiative by the Ministry of State for Antiquities to preserve the tombs in the Valley of the Kings. Accordingly, virtual tours, traveling exhibitions, and reconstructions are offered as an alternative to visiting the increasingly fragile Lascaux Cave Paintings in France. The most recently opened reconstruction is the Montignac–Lascaux International Parietal Art Center, or Lascaux 4, which employs different set designs, displays, state-of-the-art interactive workshops, and immersive technology to bring the paintings to life. Visitors have commented that the atmosphere inside the replica cave is just like that of a real cave: dark, damp, and muffled.

Archaeological “voluntourism” also has been growing in popularity as an on-site participatory activity for tourists. It is increasingly common for archaeological excavations to be fully or partly funded by nonspecialist participants. More recently some excavations can also be followed online, which gives prospective “voluntourists” an idea of what is involved in digging.

People are a very important aspect of information provision and in creating memorable tourism experiences. A professional guide can provide additional information to a tourist by contextualizing the site with visual aids. Often, simple methods work best, such as having some historic photos or plans to hand that can be used to show change over time, and are particularly useful for archaeological sites with long-running excavations.

Evaluation and feedback mechanisms

Evaluation and feedback mechanisms form the last step of a current planning process and the

first of a subsequent planning round. These mechanisms enable archaeological site managers to track success towards the goal achievement. As a minimum, experiential aspects of the attraction should be assessed through visitor satisfaction surveys, monitoring of social media, or other mechanisms. In addition, tourism impacts should be monitored by regular data collection for a longitudinal study (du Cros and McKercher 2015).

Finally, it should be noted that the work does not stop once an archaeological site is developed to its full potential for cultural tourism. Business models and budgetary planning should take into account the behind-the-scenes costs of maintenance, improvements to interpretation, archaeological site presentation, staff training, and other ongoing expenses as an ongoing process.

Future directions for planning and tourism

Along with further accommodation of technological change, attraction managers will have to contend with measures to adapt to climate change. Research in the United Kingdom has noted the need to establish a distinction between sudden, extreme events and long-term trends in order to develop strategies applicable to the wide variety of effects of climate change. It has been suggested that lack of long-term budgetary planning for managing and monitoring climate change impacts is becoming more of a critical issue for many heritage attractions (Hall et al. 2016). Stakeholder readiness to engage with these challenges varies immensely. Research is ongoing into the factors involved in barriers to stakeholder readiness to engage in these matters.

Plurality and Multivocality

RHIANEDD SMITH

University of Reading, UK

Archaeology has meaning not only for archaeologists. Pluralistic and multivocal approaches explicitly recognize the diversity of archaeology's stakeholders and question who should be allowed to speak for the past. They are political and theoretical positions rather than clearly defined methods, although they have generated new theoretical and methodological approaches too (Wylie 2015). Multivocality has moved beyond simply being a way of presenting or communicating and can be used to refer to an epistemological debate, a style of archaeological writing, a form of representation, field practice—or, ideally, all of the above.

The rise of multivocal approaches in archaeology can be situated within the rise of critical theory, postmodern, feminist, and postprocessualist critiques of archaeology. Theorists in this field have questioned the neutrality of the archaeological method by recounting the discipline's relationship with nation-state formation and its exclusion of certain voices (Fawcett, Habu, and Matsunaga 2008). Multivocality and pluralism are approaches that attempt not only to critique past and current practice, but to build a more hermeneutic experimental model. Meskell (2012) uses the term “hybrid fieldwork” to refer to an increasing blurring of disciplinary boundaries. Archaeologists now excavate archives, conduct ethnographic work on heritage, investigate media-based productions of knowledge, and work with living communities (Meskell 2012).

Multivocality is also a reaction to wider cultural shifts outside of the discipline, most notably the growing strength of “indigenous” and descendant voices in debates regarding cultural patrimony (Colley 2002; Sillar 2005). At its best, multivocal and pluralist archaeology represents a move toward a proactive rather than reactive approach to indigenous calls for consultation,

co-curation, and repatriation or reburial (Atalay 2008). However, archaeologists also need to be aware of the legacies of marginalization and exploitation, which they may inherit when trying to establish collaborative partnerships. Rhetoric regarding “other” voices in archaeology has traditionally focused on repatriation and reburial claims (Sillar 2005). However, multivocality, or “deep reflexivity” (Atalay 2008) involves radically rethinking the way in which archaeology is practiced, so that the entire process of interpretation is subject to analysis.

Multivocality and pluralism are less rulebooks and more umbrella terms that may be used to inform and describe wider debate and myriad types of research projects. Wylie (2015) differentiates between “syncretic pluralism,” where indigenous and scientific ways of knowing might be respected but are mutually exclusive, and “dynamic pluralism,” where indigenous ways of knowing may enrich scientific research. Appreciating the ability of oral traditions to preserve historical information is a case in point. In practice, multivocality and pluralism exist on a continuum or, more accurately, in a negotiated space where various types of fieldwork, ethnography, activism, and interpretation may overlap in different formations. It should also be an iterative process, as trust is built, power is shared, and practice is informed.

This type of approach has been popular with historical archaeologists in regions where engagement with living communities may inform the interpretive process in academically valued ways (Fawcett, Habu, and Matsunaga 2008). It has also become a necessity in places where the permission of descendant communities is a required element of access to archaeological resources (Colley 2002). However, the concept of a “first voice” or “originating community” can imply that, for an archaeological resource, there is a single true indigenous community that has a shared viewpoint.

A focus on the notion of legal genetic descent as the primary method of attributing rights can in fact be used to deny rights. “Indigeneity” is

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0466

not an unproblematic concept, and official definitions can deny the complexity of postcolonial encounters and the agency of the communities in question (Sillar 2005). Definitions reliant on genetic descent have been used to disenfranchise groups that have long histories of migration or genetic “mixing,” or where time depth makes it impossible to identify direct descendants (Sillar 2005; Colley 2002). A focus on indigeneity can overlook issues of power, class, and local context within and beyond indigenous groups. There are also stakeholders who have shared histories of disenfranchisement but are not defined primarily by genetics or by their relationship with colonial encounter, for example working-class communities. Simplistic applications of multivocality summon up a false notion of one cohesive community, which lacks professional knowledge but brings indigenous “truth” in a way that is impractical, inaccurate, and offensive.

The notion of a shared community, or even of a family voice, simplifies the complex nature of cultural and historical affiliation and overlooks current research into the nature of identity (Atalay 2008). The idea of working with “a community” suggests a “them and us” in total consensus with each other. In multivocal accounts differences between voices may have to be compressed to create coherence out of a complex and ever-shifting picture. There may be imbalances of power related to education, gender, age, and family connections. For example, the mayor of a town may have a radically different viewpoint, access to power, and agenda from those of marginalized groups who live near a site, even though the latter could arguably be said to be from the same community. One person is unable to speak for a whole group. Stakeholders may be highly educated and politically astute and may have their own agenda (Atalay 2008). While multivocality and pluralism require the researcher to be an activist, s/he must work within local politics, for there is an arrogance in assuming that only outsiders can “give voice.”

Hodder (2005) argues that, when dealing with the existence of multiple stakeholders, there are two common reactions: policing the borders of the discipline against antiscientific interpretations; and adding other voices only in public interpretations. This second approach takes into account other voices but still keeps

them separate from the process of research. Examples of deeper collaborative and multivocal archaeological research exist on a continuum, and the degree of pluralism may depend in part on local context and politics. In some cases the entire research process can be shaped through collaboration: nonarchaeologists would set the research agenda from the start. The adoption of multivocal approaches happens mostly in historical archaeology, where different forms of evidence may intersect, and in “settler countries,” where the voices of different groups of descendants interact with those of ancestors and their material remains.

However, multivocality can also be seen in prehistoric archaeology, where a variety of stakeholders may express a spiritual or genetic link with communities long gone. Çatalhöyük is the site with the largest and longest running archaeological research project that is explicitly multivocal. In this instance multivocality recognizes that there might not be one community and that a site’s significance may cross religious, local, national, and international boundaries. Hodder (2005) also stresses that multivocality may take place in the very act of excavating. For example, decisions regarding where to excavate or how to take samples might be influenced by the specialisms, theoretical interests, and local practices of individual members of the team. Hence, if archaeologists were to hand over “pure data” to people outside the team in order to access other voices, that would still encompass certain assumed categories and processes (Hodder 2005). Such discussions prompted the development of a reflexive method at Çatalhöyük in which archaeologists questioned the nature of interpretation not only at the visitor center but in their sampling techniques, cataloguing, and finds analysis (Atalay 2008; Hodder 2005). This destabilized the divide between raw or pure data and subjective interpretations. At Çatalhöyük, site visits also allow lab technicians and fieldworkers to discuss priorities and to reflect upon the decision-making process that underlies their work and the different techniques used in different areas (Hodder 2005).

These interpretive discussions are recorded in videos and diaries, so that researchers are able to examine the context in which data are produced, both as they are conducting the research

and at a later date. These “rich descriptions” are interrelated via an integrated database. The Çatalhöyük database is available online, in an attempt to engage diverse groups in the process of interpreting the data. However, Hodder (2005) himself acknowledges that this technique of democratizing the interpretation is not without its flaws and that a great deal of archaeological data are incomprehensible to nonexperts.

Critiques of pluralism note the threat that engagement might make to scientific objectivity. Multivocal and pluralistic approaches have also been criticized for creating space for voices that might seek to oppress or misinform (see Wylie 2015 for discussion). The difficult question of who ultimately wields power or leads the process of collaboration in any given multivocal dialogue is something that is acutely realized by most of those who engage with these kinds of practices (Bender 1999).

Next, multivocality has been criticized for its lack of engagement with concepts of power. Identity is situational and intersectional; if research is to be truly multivocal, then conflicts and tensions need to be acknowledged and communicated. Attempts at multivocal interpretation can give a voice but involve no redistribution of the underlying power; in fact they may even consolidate underlying power imbalances by suggesting cohesion where inequality is rife.

One persistent challenge to pluralistic practices is how they are organized, recorded, and disseminated. Peer-reviewed academic articles are still the primary way in which practice is valued and consumed beyond a local level. This may exclude nonacademic participants or devalue nonacademic forms of communication. In her examination of archaeological forms of language, Rosemary Joyce (2002) uses Mikhail Bakhtin’s concept of “polyphony” to highlight the problems with many attempts to capture multivoicedness. In polyphony, multiple voices with their own autonomy and strength are engaged in an open-ended dialogue, but this is not always achieved in self-conscious attempts to co-opt other voices into archaeological texts.

The representation of multivocality to the public is not without its challenges either. Within heritage interpretation, the importance of participatory practice is recognized by professionals and funders, although the term multivocality is rarely

used. Multiple interpretive outcomes are used, with the medium chosen collaboratively, to suit the group in question. However, the style of representation may unintentionally marginalize or “mark” voices as unofficial. Permanent-looking text-based forms of interpretation, which obscure authorship through the use of the passive voice, may be seen as more reliable than creative or unorthodox forms of interpretation. Nonprofessionals may also actively adopt what they see as official forms of expression, out of a wish to legitimize their work or censor their own histories for an outside audience (Bender 1999).

Multivocality and pluralistic ways of working thus require relinquishing control while still trying to deliver shared outcomes. A research team needs to be self-critical and honest about failure and false starts, rather than shouting only about success stories. Taken to an extreme, this way of working involves an acknowledgment that nonarchaeologists are a part of the team and not just there to be consulted. This kind of archaeology is a challenging, messy, and iterative process of dialogue, participation, and experimentation; it is not a box-ticking exercise.

Public Archaeology

GABRIEL MOSHENSKA

University College London, UK

CHIARA ZUANNI

University of Graz, Austria

For as long as there have been remains of past people and societies, there have been scholars and members of the public fascinated by these traces. Since the beginning of the discipline, archaeologists have found appreciative members of the public keen to see them work, hear them speak, and read their words. The foundations of public archaeology lie in the efforts of early archaeologists to encourage, shape, and exploit this widespread and intense popular interest. Today, public archaeology is a thriving subdiscipline that seeks to encourage, equip, and enable archaeologists to share their work with public audiences, while also turning a critical eye to the places where practitioner and public meet and interact. As archaeology has moved from the realm of the amateur into the more regulated worlds of government, industry, and academia, the need for communication and understanding across boundaries of public and private has become ever more clear and urgent.

The definition of public archaeology is hard to pin down, and due to the often very different national traditions of the term in the United Kingdom, the United States, and elsewhere it is perhaps better to speak of a cluster of definitions. It is important to note that most of the practices now included within the broad term public archaeology predate its first use by decades or even centuries. A book entitled *Public Archaeology* published in the United States by Charles McGimsey (1972) identified it as archaeology carried out by state and official bodies on behalf of the public, and this definition remains a central and important one, particularly in relation to the work of state and nonstate environmental, heritage, and landscape management bodies

such as the US National Park Service. State heritage agencies and related nonprofit and non-governmental organizations (NGOs) remain the principal employers, supporters, and funders of public archaeology around the world.

Due to the difficulty in defining public archaeology, scholars have tried to categorize and identify the main themes within the field. Drawing on concepts from the field of science communication, Merriman (2004) distinguished the “deficit model,” based on educating the public about archaeology, from the “multiple perspectives model” that encourages collaboration and co-creation. Okamura and Matsuda (2011) further divided this typology, noting that within the practice-focused dimension of public archaeology, which builds upon Merriman’s deficit model, there is both an educational dimension aimed at informing the public, and a public relations approach aimed at raising the profile of archaeology in the public sphere, including political lobbying in support of heritage protection. On the more academic side of public archaeology, they further identified a critical approach drawing on social theory that examines the place and function of archaeology in the real world, for example in relation to postcolonial and radical political movements, and a multivocal approach that focuses on exploring and promoting diversity and pluralism in the study and presentation of the human past. These studies of the nature of public archaeology are important in that they highlight the division within the discipline: on the one hand, public archaeology is a field of scholarship with an extensive and well-developed critical discourse; on the other hand, it is a profession based on the development and use of a distinct set of skills and expertise.

There is a long tradition of archaeologists communicating their work to the interested public through a variety of media. One of the earliest examples of this was Austen Henry Layard’s excavations at Nimrud in the 1840s which led to the publication of *Nineveh and its Remains* (Layard 1849), which linked Layard’s discoveries to biblical history and captured the public imagination.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

Between the nineteenth and twentieth centuries, coverage of archaeological work in popular outlets also helped to fund the excavations: Heinrich Schliemann wrote regularly for major European newspapers, while Howard Carter's work was closely followed by journalists.

Beside reading about archaeologists' work in the press and popular books and following the process on television, excavations themselves have attracted the attention of curious passers-by since at least the eighteenth century, when one British antiquarian described himself as "plagued" by interested locals, while Egyptologist Flinders Petrie famously dug wearing a flesh-toned outfit in the hope that his apparent nudity would deter visitors from approaching. Others were less reticent: the monumental excavations at Maiden Castle, Dorset, England in the 1930s saw director Mortimer Wheeler encouraging public visits, arranging tours and lectures, and selling artifacts and postcards as souvenirs. Since the 1980s, the large international research project at Çatalhöyük has explored different ways of including and engaging the different community stakeholders in their work, and, despite the emergence of new media, site visits and tours remain an important element of public archaeology.

Many of the practices of public archaeologists are also described under the term "community archaeology," and they are often used interchangeably (see *COMMUNITY HERITAGE* and *HERITAGE AND COMMUNITY ARCHAEOLOGY*). Community archaeology tends to refer to work that includes interested nonprofessionals in the archaeological process, including as excavators. One of the earliest and most remarkable community archaeology projects was the Tsukinowa burial mound excavation in Japan, begun in 1953. This project was led by academic archaeologists from Okayama University who aimed—drawing on explicitly socialist ideals—to include people of a wide range of ages and backgrounds in the excavation. Ultimately, more than 10,000 people took part, including archaeologists, teachers, students, and local people.

One of the most disconcerting parts of working in public archaeology is the discovery that most of the public obtain their understanding of archaeology and the work of archaeologists from a range of cultural references, ranging from the painfully outdated to the utterly deranged

(Holtorf 2005). The study of cultural representations of archaeology might seem like an excuse to read comics and watch movies, but it offers vital insights into popular engagement with the human past. Some argue that the high profile of archaeology in popular culture is largely a positive, while others raise concerns about outdated and potentially exclusionary stereotypes, which might ultimately harm the cause of public archaeology.

Historians of archaeology have highlighted the fact that many attempts at communicating archaeology to the public have been part of deliberate campaigns of nationalist propaganda (see *HERITAGE AND NATIONALISM*). In these cases, appeals to a shared, glorious ancient ancestry have been used to bind together a geographic population into a nation or people. The newly independent nation of Pakistan hired Mortimer Wheeler to present an ancient pedigree for a new country with his book *Five Thousand Years of Pakistan* (1950), while Southern Rhodesia renamed itself Zimbabwe after its most famous archaeological monument, taking its national flag and symbol from the carved stone bird artifacts found at the site.

The close connections between archaeology, nationalism, and colonialism saw a backlash in the 1980s, encouraged in part by the controversial first World Archaeological Congress in 1986. Members of indigenous populations and formerly colonized nations around the world demanded an ethical discourse in archaeology that recognized their cultural property and rights. In North America and Australia, these debates focused heavily on human remains held in archaeological collections and museums, and campaigns for their return and reburial led to the passage in 1990 of the landmark US Native American Graves Protection and Repatriation Act. In other cases, campaigns focused on the repatriation of stolen cultural objects from museums have been less successful, such as the requests that the British Museum return the Benin Bronzes to Nigeria; for some time there has been an intense debate in the museum world surrounding these issues (see *CRITICAL MUSEOLOGY* and *REPATRIATION*).

The looting of archaeological sites remains a lively issue in public archaeology, particularly in areas such as Italy and Egypt, where artifacts can reach high prices from unprincipled collectors.

The most vulnerable archaeological sites are those in conflict zones such as (at the time of writing) Iraq, Syria, and Yemen, often targeted for deliberate destruction. At the same time, looting archaeological sites can be an opportunistic crime by poor and vulnerable people looking for ways to survive. Ethical debates in archaeology are a central part of public archaeology discourse, and issues around the protection of heritage sites in conflict are some of the most salient and controversial. Should archaeologists work with military-occupying forces to protect cultural heritage? Should we turn a blind eye to looters who would otherwise be unable to feed their families? How do we value heritage compared to human lives? The debates around these questions where archaeology meets the rest of the world are at the core of contemporary archaeology (see HERITAGE AND HUMAN RIGHTS AND HERITAGE ETHICS).

Public archaeology is growing in several different directions, and the future of the field looks strong. The concept of “citizen science” is starting to affect our understanding of the roles that the public can play in archaeological work. Amateur archaeologists are monitoring the erosion of coastal heritage sites, reporting metal-detecting finds to national databases, helping to transcribe and digitize old archives, and engaging in conservation projects, in collaboration with academics, museums, government bodies, and heritage professionals (see RESPONSIBLE METAL DETECTING). One of the most powerful tools in this growth of public archaeology has been the use of digital resources, both as a means of sharing archaeological data with the public and as a way for the public in turn to add and contribute (Bonacchi 2012). Archaeologists are asking the public for help monitoring satellite images of endangered sites for signs of looting, while some remote or inaccessible excavations are providing webcams so that interested people all over the world can watch the work progress. Digital media are broadening-out public archaeology: where previously a few archaeologists might write for a popular audience, it is now far easier to disseminate information, including regular updates on work and discoveries. Museums and collections are also using digital media to open up archives that would otherwise remain hidden to visitors.

Public archaeology today is exploring new ways of using digital media in practice: one of the emerging challenges for public archaeologists is to maintain critical analyses of these digital encounters between the public and archaeology. Hopefully these new ideas and approaches to a well-established field will provide new contributions to the long-standing discourses around values, ethics, education, participation, repatriation, ownership, and identity.

Re-Enactment and Engagement

MADS DAUGBJERG

Aarhus University, Denmark

Re-enactment is a term covering a wide array of different activities related to the staging and animation of selected fragments of the past in the present. The re-enactment activities within archaeology and the heritage sector, typically performed by costumed participants (re-enactors) in front of an audience, are sometimes referred to as “historical” re-enactment in order to distinguish them from other disciplines’ use of the term and method. In film studies, theatre studies, and media studies, for example, “re-enactment” is generally used to describe the reviving or restaging of older pictures, formats, or events on stage or in front of the camera. Although there are overlaps, for example when filmic re-enactments include groups of historical re-enactors hired as extras, the present discussion concentrates on historical re-enactment as it is practiced within the heritage sector.

Typical examples include re-enacted battles and other pivotal events such as historical speeches, protest gatherings, marches, ship journeys, slave auctions, and courtroom sessions. While some reserve the term re-enactment strictly for those instances in which a precise historical moment is being restaged—for example, the 1620 landing of the *Mayflower* or the 1815 Battle of Waterloo—in its common usage it also covers more generic heritage or “period” activities, such as Viking or medieval markets, craft and culinary demonstrations, or World War II encampments and air shows. Some insist that such nonspecific elicitations should be labeled “living history” activities and not re-enactments.

It is common to view historical re-enactment and living history contexts as particularly accessible and engaging educational settings, catering to audiences unaccustomed to more conventional,

academic modes of appropriation. Proponents of re-enactment-based approaches stress the three-dimensional and multisensory quality of the experience, the possibility of dialogic engagement between re-enactors and audiences, and the chance to work physically and materially with historical or archaeological traces and theories—with implicit or explicit connections to the genre of experimental archaeology. Conversely, critics have pointed to the dangers of uncontrolled experimentation and play, conjectural dramatization, and the tendency among some re-enactors to focus heavily on material details (such as weapon types, uniform buttons, sewing styles) while ignoring larger historical or political contexts. In some cases, strong commercial and tourist-oriented agendas influence the alleged educational or scientific outcome. Indeed, this is a field in which a strict upholding of boundaries—for instance between entertainment and education, between the production and the consumption of heritage, or between experimental and experiential modes of engagement—can be very hard to control.

Historical context

Re-enactment is not new. In one form or another, the human need to narrate and perform “what happened” in other times to an audience is probably as old as humankind itself, and so are the surrounding debates about the historical accuracy of each new performance. In ancient Rome, imperial victories in faraway lands were often restaged for the public, including alleged cases of spectacular naval battles in which the Colosseum was flooded. In many religions, foundational stories and rituals have survived in forms with obvious re-enactment traits, such as the widespread Good Friday recreations of the Crucifixion of Christ, the Islamic *hajj* pilgrimages to Mecca, and Buddhist rites based on rigorous replication of ancient procedures. The proposed connections in such religious practices between

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0499

corporeal imitation and inner experience can be likened to the strivings of modern re-enactors, who often claim to have been touched or moved by “history” through their bodily and material efforts.

During the late nineteenth century and early twentieth century, as new paradigms of exhibition and entertainment developed across the western world, the use of re-enactment-style demonstrations became increasingly popular. The World Fairs and Great Exhibitions of the period often included folk exhibitions in which “savages” and other colonial subjects were employed to typify “exotic” cultures under western domination, supporting the racialized hierarchies of the era. In the traveling Wild West shows, organized by entrepreneurs like William “Buffalo Bill” Cody from the 1880s onwards, key battles and episodes from the American Indian Wars were replayed in circus-like frameworks in which Native Americans performed as (stereotypes of) themselves. Meanwhile, the open air museum movement, emanating from Scandinavia in the same period, popularized exhibition principles known also from the World Fairs, including the idea of reconstructed “interiors” that could be manned with mannequins or, later, live people.

In 1920, in the recently formed Soviet Union, a grand re-enactment of the 1917 Storming of the Winter Palace in Petrograd (today’s St Petersburg) was staged, involving Vladimir Lenin himself. In turn, this simulation inspired key scenes of Sergei Eisenstein’s 1928 propaganda film *October*, which, over the years, came to be viewed in the USSR as the legitimate historical representation of the event. In twentieth-century the United States, the recurring anniversaries of the American Civil War, and especially of the (1863) Battle of Gettysburg, became key nodes for the development of re-enactment as a genre of mass commemoration. The fiftieth Gettysburg anniversary in 1913 was billed as a “reunion” between North and South, but it is the 1963 centennial that is usually seen as the birth of modern-era re-enactment. Today, besides the still popular American Civil War scene, major battle re-enactment societies include practitioners of Viking, Medieval, English Civil War, Napoleonic, and World War I and II history.

Appeal and engagement

The bodily, tangible, and interactive possibilities of re-enactment set it apart from most other kinds of engagement with historical material. Advocates of re-enactment and living history stress these qualities as fundamental to the method’s public appeal and the educational possibilities it holds. Even though most materials used for re-enactment are reproductions rather than original historical artifacts, the genre’s orientation towards haptic and tactile engagement makes it well suited to trigger debates belonging to a different register than those derivable from text- or exhibition-based learning. Immersing oneself in the restaging of past events may provoke questions of movement, posture, and emotion, potentially pushing the performer to reflect upon the past in a new light. Such kinds of engagement display obvious parallels with other phenomenological approaches in archaeology, in which subjective and experiential dimensions are accorded similar academic credence. Under the right circumstances, re-enactment sessions hold an educational value difficult to obtain through conventional learning. Indeed, several primary- and secondary-level educational programs make use of some variety of re-enactment, for example by training students to simulate and respond to historical events on the basis of prior reading of source materials.

Re-enactments, wherever they are performed, can never guarantee full historical accuracy or objectivity. Conditions are almost inevitably uncontrollable, and commercial, political, or other agendas threaten to obscure the relationship between the original event and its resurrection. Furthermore, although re-enactors are generally intensely preoccupied with “authenticity”—taking this ideal to entail, most often, a material and visual likeness of the past—it is rarely hard for critics to point out aspects not in accordance with the historical record. Given this impossibility of full historical perfection, one may seek to escape such an authenticity-bound framework by viewing re-enactment and its appeal in a different light: as a genre of historical commitment with the potential to facilitate a particular kind of resonance and sensitivity towards selected elements and conditions of the

past. Re-enactments, through their intentional reworking, can sometimes breathe new life into or challenge established understandings or cultural practices, and may also provide minorities or underprivileged groups with a voice in the telling and retelling of history.

Key debates and problems

The quest for authenticity, and the question of what one should take an “authentic” performance, battle, or object to mean in the first place, is a foundational debate among re-enactors. While it is obvious that there can be no full 1:1 resemblances between then and now, a strong urge towards getting “as close as possible” to something of “what it must have been like” remains the ideal. Some re-enactors speak of “magic moments” or “period rush”—flashes of time in which the barrier between now and then seems to break down and afford almost revelatory experiences. On a less subjective level, authenticity issues emerge constantly: for example, whenever decisions must be made as to whether or not certain textiles or uniforms can be allowed, whether one should speak in the first or the third person when addressing an audience, or when a particular battle scenario and its historical basis are discussed. Several commentators have sought to distinguish between different meanings of the notion of authenticity, to better grasp the assumptions and agendas underlying various invocations of the term.

Given that battle re-enactments constitute such a key part of the living history scene, the understandings and images of history ingrained in it have been accused of being militaristic, masculine-centered, and, in some cases, overtly patriotic or nationalist. It is surely the case that this is a male-dominated field driven by a passion for war history. Although quantitative data are scarce, most studies agree that re-enactment groups are dominated by participants with politically conservative stances. While it is undeniable that some re-enactment societies are saturated with right-wing attitudes—from American “Odinist” Viking groups to Russian “military-patriotic” youth educational camps—one should take care not to mechanically

equate re-enactment as a practice or method with orthodox ideologies. As a tool for engagement with the past, re-enactment has also been utilized to mobilize protest and the struggles of the weak, for instance in lynching scenarios performed in the US South and in revivals of the 1989 revolutionary marches across eastern Europe.

While some scholars uphold a critical view of re-enactment, stressing the risk of hollow, superficial, politically dubious, or commercialized performances, others have explored these phenomena for their performative and educational power and the ways in which they can provide individuals and groups with agency and resonance. These are also debates on authority and expertise; on whether the kind of visceral engagement with the past that re-enactment offers amounts to historical knowledge of a legitimate kind. In today’s experientially saturated cultural landscape, where many museums and other cultural institutions employ re-enactors and living history groups—many of whom are volunteers—these issues can be pressing. In some cases, especially when it comes to dealing with recent historical periods, they are entangled with complex ethical questions: Is it acceptable, for instance, to re-enact Nazi militarism or to flag the Confederate colors during a re-enactment of the American Civil War? Are performances to be likened to theatre plays, where re-enactors merely play “roles”—or are they also, in fact, political expressions of identification and sympathy? While participants will most often argue that they are simply performing historical episodes as faithfully as possible, re-enactments can be divisive rather than enlightening, especially in cases when accounts and facts are strongly contested. These questions keep sticking to the genre, especially in its military forms, testifying to the gray zone re-enactment inhabits in which personal incentives and identifications, playful leisure settings, and institutional or scientific interests intersect. They serve as a reminder that any reinterpretation of history, as it ascribes new meaning and power to the past, is always already infused with political positioning and thorny issues of representation.

Repatriation

MOIRA SIMPSON

Evocative Art and Heritage, Australia

Repatriation refers to the return to the country, community, or tribe of origin of cultural heritage and ancestral remains which were acquired by museums, collecting institutions, or private collectors prior to the introduction of heritage protection laws. Since the 1960s, it has become an international issue of significance to archaeology, anthropology, and museology because of efforts of nations and communities to reclaim items that were acquired by various means including plundering, looting, purchase, trade, and excavation.

Imperial expansionism was a primary mechanism for acquisition of vast collections of cultural materials now housed in museums in colonizing countries. Many repatriation claims relate to materials acquired during European colonization in the Americas, Australasia, Africa, and India, and Japan's colonial occupation of Korea.

Repatriation also relates to the return of antiquities that were acquired prior to heritage protection laws when nations permitted excavation of archaeological sites by researchers from overseas. Through a system of partage, archaeological teams were able to export a portion of collections to the museums, universities, or private collectors that funded the excavations, sometimes for a specified loan period. These were not always returned and so became the subject of repatriation claims.

The term restitution is used to refer to the return of materials that were taken illicitly after the introduction of national and international legislation to protect cultural heritage. In recent decades, many countries have introduced national legislation to prohibit looting and unauthorized exportation, which results in physical damage to monuments, as well as loss of the cultural heritage of descendant communities, and information of historical, scientific, and artistic importance. At an international level, the

United Nations (UN) adopted the 1970 UNESCO Convention on the Means of Prohibiting and Preventing the Illicit Import, Export, and Transfer of Ownership of Cultural Property. Efforts have also been made to establish international rules of war to protect cultural property in private homes, places of worship, and public institutions. Despite these efforts, monuments, museums, libraries, and archives in conflict zones continue to be targeted for looting or destruction and, with a highly lucrative international market for art and antiquities, archaeological sites across the world remain susceptible to looting.

While collectors, auction houses, and museums endeavor to establish accurate and legitimate provenance of potential acquisitions, verifying the past history of ownership is complex, made more difficult by falsified records created by unscrupulous dealers, and some museums have had to return purchased objects later found to have been looted and illicitly trafficked.

Human remains

Museum collections of human remains include ancient Egyptian and Peruvian mummies acquired through archaeological excavations and human remains collected during the eighteenth, nineteenth, and early twentieth centuries, primarily in North America, Australia, and Africa. They were collected by medical officers, military personnel, archaeologists, and anthropologists to be used for the study of ancient civilizations, burial practices, human evolution, migration patterns, and paleopathology. Historical records provide accounts by some collectors of theft of human remains and funerary objects from burial sites and shrines, the removal of bodies from sites of violent conflict, and body parts being collected by souvenir hunters (Fforde, Hubert, and Turnbull 2002).

Indigenous people have become increasingly vocal in their criticism of western science, research, and museum practices. In statements such as the *Kari-Oca Declaration*, *The Indigenous*

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0506

Peoples' Earth Charter (1992), and the *Mataatua Declaration on Cultural and Intellectual Property Rights of Indigenous Peoples* (1993), indigenous peoples emphasized the diversity of cultural heritage, its importance to cultural identity and community well-being, the intangible and spiritual aspects of heritage, and the need for heritage protection. They asserted their cultural and intellectual rights as human rights issues, and appealed for protection of sacred and ceremonial sites, and repatriation of human remains, funerary objects, and sacred and ceremonial objects from museums.

Initially, western scientists and museums resisted repatriation claims, asserting legal ownership, the primacy of scientific research, and its importance to humankind; however, attitudinal changes and policy developments have occurred within the archaeology and museum sectors. Although the repatriation of human remains was—and to some extent remains—professionally divisive among scientists, a statement of principles was agreed by archaeologists and indigenous peoples at the World Archaeological Congress (WAC) in 1989. In 1990, the WAC adopted *Archaeological Ethics and the Treatment of the Dead* (the Vermillion Accord), requiring respectful treatment of the dead regardless of background or origin.

Domestic repatriation policy developments

Significant legislative and policy developments have occurred regarding repatriation in several countries, in most cases relating to the cultural heritage and ancestral remains of indigenous populations.

In the United States, the National Museum of the American Indian Act (1989) and the Native American Graves Protection and Repatriation Act (1990) were passed to protect Native American and Native Hawaiian ancestral remains, funerary objects, and certain categories of sacred and ceremonial objects, and establish the responsibilities of federally funded museums to source communities. These included generating inventories, informing communities of holdings, and responding to repatriation claims.

Guidelines for museums in Canada were introduced in 1992, although compliance was left

to individual museums to consider claims on a case-by-case basis. In March 2000, the Provincial Government of Alberta, Canada, enacted the First Nations' Sacred Ceremonial Objects Repatriation Act, providing a mechanism for unconditional repatriation of sacred and ceremonial objects from Glenbow Museum and the Provincial Museum of Alberta, if requested by bands of the Blackfoot Confederacy in Alberta.

In Australia, major Australian museums had ceased to display human remains or secret/sacred objects by the 1980s. The first repatriation of ancestral remains occurred in 1985, with the repatriation of the Murray Black collection from the University of Melbourne Medical School. In 1993, the Council of Australian Museum Associations (now Museums Australia) introduced guidelines relating to museums' relationships with indigenous communities and included recommendations concerning repatriation. Since then, the Australian government has funded the Return of Indigenous Cultural Property Program to support research and repatriation of secret/sacred objects in the collections of the eight national, state, and territory museums.

International repatriation

In Europe and Asia, most repatriation requests are initiated by indigenous communities in nations that were colonized or between countries that were occupied. After Greenland obtained home rule in 1979, the National Museum in Denmark (NMD) and the National Museum of Greenland agreed to split the collection of Greenlandic heritage held in the NMD and over 35,000 objects were repatriated to Greenland. Since 1983, the Greek government has been seeking the return of the Parthenon Marbles which were removed from Greece in the early nineteenth century during a period of Ottoman rule.

As a result of British imperialism, UK museums hold vast collections of antiquities, ethnographic materials, and human remains from around the world. Indigenous peoples overseas have sought the repatriation of human remains and cultural materials originating from North America, Australia, and New Zealand. The return of other significant items of cultural

heritage is being sought by governments of former British colonies: the Koh-i-noor diamond (India), the Benin bronzes (Nigeria), and the Rosetta Stone (Egypt).

In 2000, the UK Museums and Galleries Commission introduced *Restitution and Repatriation: guidelines for good practice* relating to cultural objects. Guidelines for the treatment of human remains in museums in England, Wales, and Northern Ireland are provided by the Department for Culture, Media and Sport's *Guidance for the Care of Human Remains in Museums* (2005), and in Scotland by Historic Environment Scotland's *Treatment of Human Remains in Archaeology* (2006) and Museums Galleries Scotland's *Guidelines for the Care of Human Remains in Scottish Museum Collections* (2011).

In 2013, the German Museum Association introduced *Recommendations for the Care of Human Remains in Museums and Collections*. As in Britain, these are intended to guide museums in the establishment of institutional policies.

In France, another major colonizing power, legislation was passed in 2002 and 2010, but this is limited to specific cases of repatriation of human remains to South Africa and New Zealand.

The US Department of the Interior has established a Working Group for International Repatriation of Native American Cultural Heritage to assist Native American tribes seeking assistance with repatriation of stolen, looted, or trafficked cultural heritage in museums and auction houses overseas.

The Australian government's Indigenous Repatriation Program, operated by the National Museum of Australia, assists with the return of Aboriginal and Torres Strait Islander ancestral remains from Australian and overseas museums.

The International Council of Museums (ICOM) Code of Ethics for Museums (2013) provides guidance in all aspects of museum practice including repatriation and restitution, and forms the basis of the Code of Ethics of many national museum organizations and the repatriation policies of individual museums.

Nevertheless, some of the world's major museums remain resistant to repatriation claims. In 2002, directors of 18 museums in Europe and North America signed a *Declaration on the importance and value of universal museums*, arguing

that the importance of their collections for comparative research into technological, stylistic, and artistic expressions across temporal and cultural boundaries overrides claims of source communities or nations.

Conventions adopted by the UN call for protection of cultural heritage in all forms, including intangible and spiritual heritage, and reference indigenous custodianship of human remains and sacred and ceremonial objects as human rights issues. The rights of indigenous peoples were affirmed in the *Declaration on the Rights of Indigenous Peoples* (2007) and the *World Conference on Indigenous Peoples Outcome document* (2014), exhorting States to develop mechanisms to facilitate access to and repatriation of ceremonial objects and human remains at national and international levels. In 2015, the United Nations Human Rights Council (UNHRC) called for museums and other places holding collections to "inform the relevant indigenous peoples and develop mechanisms to facilitate the return of such cultural heritage when sought by the indigenous peoples concerned" (UNHRC 2015). The United Nations Permanent Forum on Indigenous Issues (UNPFII) recommended that States and indigenous peoples "establish a working group to prepare a manual of good practice with regard to the repatriation of ceremonial objects and human remains" (UNPFII 2015).

Repatriation and its outcomes

Repatriation negotiations can lead to the establishment of collaborative relationships benefiting both museums and communities. The return of archaeological artifacts to Peru from Yale University in 2012 included a partnership agreement with the Universidad Nacional de San Antonio Abad del Cusco (UNSAAC) in which a new Center for the Study of Inca Culture would be established in Cusco to store and display the collection under a shared stewardship arrangement.

Since the late 1990s, the Haida community in British Columbia, Canada, has negotiated the repatriation of the remains of several hundred

Figure 1 Haida repatriation ceremony, 1998. Skidegate community members carrying boxes of ancestral remains from canoe on beach to Skidegate Community Hall.

Source: Haida Gwaii Museum, Canada, published with permission.

ancestors from North America museums, forming positive working relationships with some. Ancestral remains were repatriated and reburied in painted bentwood boxes made using traditional methods relearned from examination of examples in museum collections (Figure 1). In recent years, the Haida Repatriation Committee has reached out to museums in the United Kingdom, leading to collaborative projects with the Pitt Rivers Museum and the British Museum (Krpmotich and Peers 2013).

In Alberta, Canada, the Kainai (Blood Tribe of the Blackfoot Confederacy) had been seeking the return of medicine bundles since the early 1970s. During the 1990s, Glenbow Museum in Calgary and the Provincial Museum of Alberta in Edmonton were lending sacred bundles to Blackfoot ceremonialists for use in ceremonies essential to the continuation of Blackfoot world views. Through relationships built over a number of years, museum staff developed greater insights into cultural and ceremonial life and the importance of the bundles, and produced collaborative exhibitions with the Blackfoot communities. In January 2000, 251 artifacts, including a number of ceremonial bundles, were transferred

unconditionally from Glenbow Museum to the Blood, Peigan, and Siksika communities.

Responsible Metal Detecting

SUZIE THOMAS

University of Helsinki, Finland

Among the different forms of artifact hunting, hobbyist metal detecting has been of particular interest in recent years to researchers, especially in regions such as northern Europe where metal artifacts are in relative abundance and where laws do not prohibit metal detecting. Countries that have fuller restrictions, such as Cyprus (Hardy 2014), often also have more extensive state intervention regarding cultural heritage in general, such as the state ownership of cultural objects, or have experienced an incident that has affected opinion concerning the acceptability of metal detecting as a hobby, as with Ireland (Kelly 1993).

Metal detecting emerged as a hobby in which members of the public could partake, in countries such as the United Kingdom and the United States in the 1960s, although metal-detecting devices—originally developed in the military for mine searching—had been available before then. There is evidence of archaeologists trying metal detectors in the mid-twentieth century, such as in England in 1948 (Hobbs 2003, 18) and the United States in 1958 (Connor and Scott 1998, 76).

Despite early tests of the efficacy of metal detectors as archaeological survey tools, the devices have attracted controversy, especially in the 1970s and 1980s, with the rapid growth of hobbyist metal detecting (Thomas 2012). Incidences of looting using metal detectors, as well as tensions around the different ontologies adopted by archaeologists and other heritage professionals, and within the metal-detecting community itself, have led to conflict at different times, sometimes spilling over into broader political debates about heritage management policy.

In some countries, such as Sweden, Russia, and France, it is illegal to metal detect. This does not necessarily prevent looting, which is still a problem in many places where metal detecting

is not permitted. Some countries, such as Estonia, permit metal detecting provided the metal detectorist has applied, and fulfilled the criteria, for an official license. In other countries, such as Denmark and the United Kingdom, metal detecting is legal in many circumstances (although certain areas of land may be protected, for example if designated as a site of archaeological significance). In situations where metal detecting is permitted, hobbyists are nonetheless required to meet their legal obligations: in most cases, including New Zealand and Finland, hobbyists should not disturb known archaeological sites, and in many countries there are various levels of mandatory reporting of finds. Furthermore, the use of metal detectors in a hobbyist capacity not only relates to the search for archaeological material: Internet discussion forums in Australia and New Zealand indicate that gold prospecting is a major goal of hobbyists in those countries, for example. The legal requirements for finds recording thus vary from jurisdiction to jurisdiction, although responsible metal detectorists would be expected to report not only the objects that the law requires them to report, but also other archaeological and historical material.

Beyond often basic legal requirements, it is clear that the practices of hobbyist metal detectorists put many more objects of archaeological significance at risk. Therefore, in many jurisdictions where metal detecting is permitted, hobbyists are also encouraged to practice their hobby responsibly, to ensure that more archaeologically useful information can be gathered from their discoveries. Critics of metal detecting argue that the removal of objects by untrained detectorists cannot ever be at a standard comparable to that of a scientific investigation (e.g., Gill 2010); others have acknowledged that in certain circumstances—such as areas where land has already been plowed or otherwise disturbed—and with a responsible approach, it is still possible to salvage scientifically useful information (e.g., Kershaw 2013).

Responsible metal detecting is generally interpreted as the behavior, or best practice, of metal detectorists who adhere to a set of standard

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0507

procedures to ensure that the archaeological context of what they find is adequately and accurately recorded, and reported to the correct authorities. This may mean reporting to a local or national museum, a national heritage authority, or other organization with designated responsibility for recording finds, depending on the country or region. There are also legal restrictions on the movement of certain cultural objects across national borders, which may affect detectorists who practice their hobby in more than one country.

In England and Wales, mandatory reporting is limited only to a few categories of finds that are defined as “treasure” in the Treasure Act 1996. Since 1997, this law has been complemented by the Portable Antiquities Scheme (PAS), which began as a pilot project in six regions and was later rolled out across the whole of England and Wales. Various organizations—representing both archaeologists and metal detectorists—have contributed to and shared a Code of Responsible Metal Detecting, which was agreed and published in 2006 and updated in 2017 (<https://finds.org.uk/getinvolved/guides/codeofpractice>), and the PAS maintains a network of Finds Liaison Officers to whom detectorists are strongly urged to report finds of all types of archaeological artifacts so they can be identified and recorded scientifically. Among the ways to be “responsible” according to the Code are “[r]ecording findspots as accurately as possible for all finds (i.e. to at least a one hundred metre square, using an Ordnance Survey map or hand-held Global Positioning Systems (GPS) device) whilst in the field.” If it appears that the discovery is something more significant than a stray find—such as a hoard of artifacts or possible part of an archaeological site—metal detectorists should refrain from further excavation and contact the heritage authorities.

Many organizations also offer advice to metal detectorists on how best to conserve their finds. The crucial element of accurately recording finds with an archaeologist, as well as refraining from “cleaning” the artifacts (which will remove further contextual information from the object), has led in recent years to various countries developing their own digital databases specifically for handling the finds data that metal detectorists and other artifact collectors have available. In addition

to PAS, which began its activities in 1997 in England and Wales and has curated a finds database from its outset, in recent years databases have come into development for Flanders, Belgium, the Netherlands, and Denmark. Several other European countries are in the process of developing proposals for finds recording schemes, and there are also discussions underway in some US states for state-wide recording schemes.

In addition to “responsible” behavior—meeting minimum standards in recording, conserving, and reporting their finds—Shott and Pitblado (2015, 12) have suggested that there are also “responsive” collectors (including detectorists) that have the potential to act responsibly, pending being made aware of how their collecting activities relate to archaeological practice: “We believe that collectors who meet these minimal standards are responsible, and those who might meet them after being educated are responsive.” Therefore, while some metal detectorists may currently not be practicing their hobby in a way that makes a significant contribution to archaeological research, they may nonetheless be receptive to encouragement to metal detect in a more responsible manner, by way of advice, outreach education, and training. In Scotland, a recent series of posters and leaflets published by the Scottish Treasure Trove Unit appears to have encouraged improved finds reporting from metal detectorists and others, by highlighting what kinds of objects from different historical and archaeological periods are of interest to the Unit, and giving visual representations of how such objects typically look.

Future research around the theme of hobbyist metal detecting and its impact on archaeology seems to be developing in a number of different directions. Although much research about hobbyist metal detectorists has already taken place within national contexts—notably in the United Kingdom but also elsewhere—there is arguably a need for a yet deeper understanding of the motivations of the hobbyists themselves, which in turn may assist strategies intended to promote and encourage responsible behavior. Unlawful metal-detecting activities also continue to be a cause for concern, for example operating metal detectors in jurisdictions where it is not permitted, or not having a license in countries where it is a requirement to have one, as well as looting

archaeological sites for saleable objects. In many cases, understanding the scale of these issues is impeded by a lack of robust data—exacerbated by the clandestine nature of many of these activities.

Research projects—including doctoral dissertations but also larger-scale studies—are increasingly making use of metal-detected data. This has led to the discovery of new artifact types, studies of finds distributions over landscapes, and even identification of previously unknown or not located battlefield sites and other categories of site previously less well documented. As more digital finds databases develop, there will be challenges to ensure that these digital data are compatible across databases and systems, in order to enable and enhance transnational research questions. In addition, ethical challenges within digital finds recording include providing open-access data to researchers from within and outside of institutional academia, without compromising the security of findspots and sites: Vulnerability to looting is a serious issue to consider. Because of this, restrictions are sometimes placed on the details regarding finds location that individual users are able to access. Opportunities for research using finds databases that share information provided by metal detectorists appear to have the potential to develop further research questions and projects to utilize these “big data” as they become more readily available and accessible.

FURTHER READINGS

Value or Significance

KATE CLARK

University of Suffolk, UK

Heritage, conservation (see CONSERVATION), and cultural resources management (see CULTURAL RESOURCES MANAGEMENT) all involve taking action to prolong the life of something that might otherwise be lost, and that urge to take action is rooted in our perceptions of value or significance. The challenge is how do societies articulate that value and significance, who has authority so to do, and how, having articulated it, is it then managed?

While there are many different ways by which people identify and seek to sustain things that have value to them, this entry focuses on the articulation of value and significance in four areas: the formal designation of heritage sites; managing heritage; policy and advocacy; and heritage institutions.

Ideas about value have always underpinned laws to protect heritage, from the earliest medieval legislation on treasure to current laws (Carman 1996). However, it has only been since the 1990s that a more explicit understanding of value has sat beside the consideration of technical issues in heritage practice. Many of the heritage charters that guide heritage decision making in a European context, such as the 1931 Athens Charter for the Restoration of Historic Monuments, make brief references to value in decision making, but the 1979 Burra Charter (Australia ICOMOS 2013) was the first charter to be explicit about how an understanding of value can shape the way in which places are managed. The 2005 Faro Convention (see FARO CONVENTION) takes this a step further, by defining cultural heritage as inherited resources that reflect constantly evolving values, beliefs, knowledge, and traditions. The convention also touches on other kinds of value for heritage, including economic utility, and notes the importance of ethics in heritage practice.

Significance and value in designating heritage

The basis for formally protecting heritage sites or buildings is their collective value to people. Historic buildings and sites, including national parks, are “designated” when they are placed on a public list, schedule, or register, and that designation is recognized in law or public policy. Like other environmental constraints, heritage designation may bring benefits or restrictions for owners, which is why such lists and the criteria on which they are based are made public.

The criteria for designation are usually based on significance, which can be broken down into two elements: value (the different reasons why something is important to people) and significance (more strictly, the degree or level of that value, e.g. national importance). For sites and buildings, those values might include:

- historical interest, including association with events or significant persons;
- social or communal value;
- archaeological or evidential value—things that yield (or have the potential to yield) important information about the past;
- aesthetic (or artistic or architectural) value;
- scientific value, which may include natural heritage values;
- spiritual or symbolic value.

For conservation areas, and historic or cultural landscapes, the “special character” may be defined more widely to include issues such as identity, distinctiveness, or current uses. Sometimes cultural heritage is protected by its inclusion in natural heritage or other landscape designations.

Special interest or value need not be comfortable—sites of conscience, battlefields, and war memorials may be retained because they commemorate places of conflict and all reflect difficult historical events. The values of particular cultural groups may also be recognized; for example,

Australian federal legislation protects objects or areas of significance to Aboriginals in accordance with Aboriginal tradition.

To meet the criteria for heritage designation, sites also need to be shown to demonstrate a degree of significance that is commensurate with the weight given to preserving them in wider decision making. World Heritage Sites must be of “Outstanding Universal Value” to justify protection, and ancient monuments in the United Kingdom must be of “national importance,” whereas local heritage might simply require evidence to show that it is of local or state significance.

Advice on what to designate and why is usually provided by specialists, including anthropologists and archaeologists or indigenous community representatives, reporting in turn to an elected and publicly accountable local council, state, or national government body. Many jurisdictions allow for public consultation prior to or during the designation process, but ultimate accountability for what is protected usually lies with elected representatives.

The practical difficulty with formally protecting heritage places on the basis of their value is that perceptions of value are not static, but change with time and also in relation to other factors such as knowledge, one’s own cultural or community affiliations, and wider social, economic, and environmental issues. Sometimes they are only expressed in relation to a threat—such as a new development that might destroy cultural heritage.

Values in heritage management

Value and significance play a critical role in many of the legal, financial, and policy tools used to manage heritage places after they have been designated, such as planning policies and local plans, consent regimes, financial incentives such as tax breaks and grantaid, and management agreements (see *HERITAGE PLANNING AND DESIGN*). For publicly accessible sites, these might include park management policies, conservation management plans, heritage impact assessments, and archaeological evaluations, as well as ways of engaging with the public, including interpretation, marketing, and public programs.

As part of the process of publicly accessible sites, there is often an opportunity to explore

value in a more creative and nuanced way than is possible in the designation process. Understanding community and social values and the values of different users is often key to successfully sustaining a site (see *HERITAGE AND SOCIETY*). Equally, when dealing with proposals to change or demolish heritage sites in the planning system, heritage values need to be reconciled with other public benefits. The loss of valued heritage through development, for example, may be mitigated through an archaeological excavation that provides a public benefit by sharing knowledge.

Community engagement, mediation, and conflict resolution are increasingly important in managing heritage sites where there may be a wide range of different conflicting values (see *PLURALITY AND MULTIVOCALITY*). Heritage specialists may have a key role in helping to facilitate those conversations; alternatively, where heritage is one of many different environmental or social considerations, such as in considering new infrastructure or major developments, heritage specialists may have a more limited role.

Values in advocacy and policy development

Another kind of value arises from the benefits that flow from caring for heritage. Understanding these is of immense help in developing policies, in advocating for heritage protection, and in understanding the impact of future developments. Sometimes described as public benefits or instrumental values, these include:

- *Economic benefits:* Investing in or protecting heritage may generate new jobs or local investment. The value of private property in or near protected areas may also increase as a result of a higher quality local environment.
- *Social benefits:* Connecting with heritage or taking part in heritage activities, such as volunteering on an archaeological excavation, can provide people with new social relationships, new skills and confidence, intergenerational connections, and a greater sense of identity and inclusion; knowledge and information about the past can also be a social benefit.

- *Health benefits:* The experience of visiting sites or participating in heritage activities can bring physical and mental health benefits.
- *Environmental benefits:* Protecting heritage can deliver environmental benefits for habitats and species, as well as reductions in greenhouse gases and waste through retaining existing buildings.

These are also potentially matched by disbenefits. Owners may suffer economic harm through restrictions on development opportunities; there may be social harm where the values of certain groups are ignored or downplayed and people feel excluded; and there may be environmental harm where older buildings perform poorly in terms of thermal efficiency.

Such values can be captured through social, economic, and environmental research, including economic techniques such as “willingness to pay” surveys that monetize perceptions of value, social research into individual and group attitudes, or research into the performance of different building materials.

Ethics and values in institutions

A third kind of value is expressed through the way in which heritage specialists and organizations do business.

Caring for heritage almost always involves dealing with conflicting values, whether between different communities or different kinds of heritage, such as natural and cultural heritage. Conflicts of interest also arise in negotiating between development and preservation. Therefore, most heritage disciplines or professional groups, including archaeologists, have ethical principles or codes of conduct that govern the way in which members behave, particularly when working with groups who have different cultural values, or with antiquities which may be looted.

Equally, heritage organizations need to be able to demonstrate that they are transparent, fair, and accountable in the service that they provide to the public, in the use of public money or donations, and in the decisions that they make. Such values may be demonstrated through mission statements or codes of conduct, and in the case of larger organizations may be audited.

Debate

The articulation of value and significance in heritage has historically been grounded in the academic disciplines of archaeology, art history, social anthropology, architectural and design history, histories of technology, landscapes, and historical geography. To these have been added the expertise of people who have direct cultural associations with places, including Native American groups, first peoples, and aboriginal groups. In response to the need to work with more diverse concepts of value, heritage specialists are also turning to more collaborative techniques for exploring value, ranging from consultation and community engagement through to co-production, mediation, and conflict resolution (Myers 2016).

However, because protecting public heritage involves a process of selection, there is inevitably debate over what, why, how, and by whom things are selected. The field of “heritage studies” provides critical commentary on the way in which value is articulated, noting that heritage itself is a fluid concept. The work by Graham, Ashworth, and Tunbridge (2000) is one of several studies that chart the uses of heritage, reminding us that the values that underpin the selection of heritage sites are often rooted in wider political and social movements, such as the European nationalist movements of the late nineteenth century. Value-based heritage practice (see HERITAGE AND VALUE-BASED APPROACH) has also been criticized for objectifying and fixing certain values through categorization, and for the historical predominance of archaeological and aesthetic value over social value in assessments of significance (Jones 2017).

The study of how people value things is not just the preserve of heritage disciplines—economic models of value have dominated the field, supplemented by the recent subdisciplines of environmental, cultural, and heritage economics. However, environmental psychology, philosophy, social anthropology, and conflict studies can provide alternative perspectives on the way in which people value places and things. There are also a range of intellectual frameworks for conceptualizing value used by public policy makers to assess the benefit of intervention, including ideas

about well-being, public value, and sustainable development.

The need to reconcile a wide range of often-competing values, and the potential harm that can be done when people's values are not acknowledged, is what makes heritage management so complex and potentially divisive. Understanding and articulating value has become a central part of current practice, but the whole process of doing so is fraught and open to challenge, which is why ethics, community engagement, and the way in which value is captured and articulated has become as much of an issue for practitioners as core technical skills.

World Heritage Sites Designation

KRISTAL BUCKLEY
Deakin University, Australia

UNESCO's flagship: the 1972 World Heritage Convention

The “Convention Concerning the Protection of the World Cultural and Natural Heritage” (World Heritage Convention) was adopted by the UNESCO General Conference in November 1972. It has become the most widely recognized of UNESCO's cultural conventions, and is often referred to as UNESCO's flagship due to the prestige associated with the World Heritage List.

Amid growing concerns about the vulnerability of important places due to the effects of globalization and environmental impacts, the Convention's intent was to facilitate collective action in the face of these pressures. Like the idealistic universalizing mission of UNESCO (“building peace in the minds of men and women”), the World Heritage Convention is based on the presumption of a shared heritage. The loss of natural and cultural properties that transcend their local contexts is therefore detrimental to humanity as a whole, and the World Heritage List was established to designate properties of “Outstanding Universal Value” (OUV).

Implementation of the World Heritage Convention commenced in 1975. Entries to the World Heritage List began in 1978, with the first 12 properties inscribed from Canada, Ecuador, Ethiopia, the Federal Republic of Germany, Poland, Senegal, and the United States. Since then, the List has grown beyond the expectations of those who negotiated the Convention text (Cameron and Rössler 2013), and now consists of more than 1,000 individual properties (many of which consist of large areas of land, or contain several or even hundreds of individual sites). World Heritage properties range from single sites

to historic city centers, large landscapes, national parks, and transcontinental cultural routes.

There are currently 193 States Parties to the World Heritage Convention, bringing it to near-universal participation. The World Heritage Committee comprises 21 member states elected by the General Assembly of States Parties. The UNESCO World Heritage Centre (<http://whc.unesco.org/>) acts as the secretariat to the World Heritage Committee. Three Advisory Bodies formally contribute to the work of the World Heritage Committee, providing advice based on technical expertise: the International Union for the Conservation of Nature (IUCN), the International Council on Monuments and Sites (ICOMOS), and the International Centre for the Study of the Preservation and Restoration of Cultural Property (ICCROM).

Key concepts and processes

It is often assumed that UNESCO selects properties for inclusion in the World Heritage List, but only States Parties (national governments) can submit nominations. The nomination requirements are substantial, and the process is a significant undertaking for governments and associated communities.

The processes of nomination, evaluation, and inscription in the World Heritage List are detailed in the “Operational Guidelines” (UNESCO 2017). These have been revised more than a dozen times as the processes and concepts have evolved. The current version is 175 pages long, and additional guidance materials have been provided to assist users in navigating the requirements (for example, UNESCO 2011).

Each State Party is required to maintain a Tentative List, containing information about properties it plans to nominate to the World Heritage List in the future. A property must be included in the Tentative List for at least one year before it can be nominated.

“Outstanding Universal Value” (OUV) is the threshold and the conceptual centerpiece of

World Heritage, often described as “slippery,” evading precise definition (Labadi 2013). It is described as “cultural and/or natural significance which is so exceptional as to transcend national boundaries and to be of common importance for present and future generations of all humanity” (UNESCO 2017, par. 49). Nominations to the World Heritage List must articulate the case for OUV according to one or more of ten criteria. Nominated properties must also meet the qualifying conditions of integrity and authenticity (the latter for cultural properties only); and must have adequate legal protection and management. Community involvement is encouraged, and traditional management can be recognized. A boundary must be clearly delineated, and a further area—known as the “buffer zone”—is often established to provide additional protection for the setting of the property.

Inscription decisions are taken by the World Heritage Committee following evaluations by the IUCN (for natural values) and/or ICOMOS (for cultural values). The IUCN and ICOMOS consult relevant specialists within their networks: For example, for archaeological sites, the International Committee for Archaeological Heritage Management (ICAHM) provides input. The Advisory Bodies send a technical evaluation mission to visit the property during the evaluation process, and convene expert panels to formulate the recommendations presented to the annual session of the World Heritage Committee. The sequence of the evaluation work of the Advisory Bodies is outlined in Annex 6 of the Operational Guidelines (UNESCO 2017).

The World Heritage Committee does not always follow the recommendations of the Advisory Bodies, and the annual sessions can be the focus of considerable advocacy, media attention, and debates, both inside and outside the formalities of the meeting (Meskell and Brumann 2015). Because nominations are resource-intensive for the States Parties and involve the deployment of considerable political capital, the World Heritage Committee encourages “upstream” processes, drawing on the early advice of the Advisory Bodies so that there are fewer nominations that “experience significant problems during the evaluation process” (UNESCO 2017, par. 122). Typically, the inscription of a property on the

World Heritage List is the culmination of years of work for many people, and is joyfully celebrated.

Once inscribed on the World Heritage List, the State Party is responsible for the long-term protection, conservation, and presentation of the property. Monitoring the implementation and effectiveness of management and protection is therefore centrally important. States Parties are required to contribute to Periodic Reporting (approximately every six years). Where new developments and pressures are identified by the States Parties or civil society, State of Conservation reports can be requested and considered by the World Heritage Committee. In many cases, a Reactive Monitoring Mission, comprised of representatives of the Advisory Bodies and UNESCO, is invited to visit the property to better understand the issues, and to assist with the development of strategies for reducing the pressures and strengthening conservation.

In situations where the state of conservation is threatened by serious existing (“ascertained”) or potential pressures, the World Heritage Committee can include the property on the List of World Heritage in Danger. This decision is not taken lightly. States Parties often resist the application of this mechanism, considering it to be a sanction or criticism, even though the Convention established Danger Listing as a means of enhancing cooperation and resources where most needed. The “desired state of conservation” needed to remove a property from the Danger List is determined, along with relevant measures. The frequency of monitoring is increased for these properties, but it is nevertheless common for properties to remain designated in this way for long periods, due to the complexity and severity of the pressures. In rare instances, where it is determined that the OUV has been lost, the World Heritage Committee can remove properties from the World Heritage List. To date, this has occurred only twice, with the delisting of the Arabian Oryx Sanctuary in Oman (2007) and Germany’s Dresden Elbe Valley (2009).

Twenty-first-century tensions

World Heritage has been a focus of the emerging academic field of critical heritage, and has been analyzed by academic researchers from various

disciplinary perspectives (Meskell and Brumann 2015). The universalizing conceptual framework has been characterized as an authorizing discourse (see *AUTHORIZED HERITAGE DISCOURSE*) that privileges the role of experts and western notions of tangible heritage.

The Eurocentric conceptual framing of the Convention emerged as a tension at an early stage, but remains a pressing concern due to various entrenched gaps and imbalances in the World Heritage List. For example, the UNESCO region of “Europe and North America” accounts for close to half of the List. Since 1994, efforts to address these issues have been advanced by the “Global Strategy for a Representative, Balanced, and Credible World Heritage List,” including revisions to the criteria for inscription to reflect diverse understandings of heritage (Jokilehto 2008). Cultural diversity and inclusion remain unresolved points of tension; and “OUV,” “authenticity,” and “integrity” are contested concepts (Stovel 2007; Labadi 2013).

While the World Heritage Convention is praised for bringing the protection of natural and cultural heritage together in a single international instrument, World Heritage practices have demonstrated a clear segregation between them. Properties can be recognized for both cultural and natural values (“mixed” properties), yet these are relatively rare, and there are many more cultural than natural properties in the World Heritage List. In 1992, the introduction of “cultural landscapes” (the combined works of nature and humanity) sought to blur the nature/culture divide, but these are evaluated using the cultural criteria.

The definitions of “natural heritage” and “cultural heritage” are an obstacle for non-western cultures that view nature and culture as inseparable. Requirements for the “Free, Prior, and Informed Consent” of associated indigenous peoples were incorporated into the Operational Guidelines in 2015, and the articulation of rights-based approaches (see *HERITAGE AND HUMAN RIGHTS*) has accentuated the need for mechanisms within World Heritage that move beyond the separate nomination, evaluation, and protection of “nature” and “culture.”

The ballooning size of the World Heritage List and expanding notions of “heritage” have created

diverse notions about what constitutes protection and conservation, and increased interest in the discourse of sustainable development (see *HERITAGE AND SUSTAINABILITY*). Climate change, poverty, infrastructure, and rapid urbanization often factor in the state of conservation of listed properties.

Tourism interest and development can follow World Heritage listing (see *ARCHAEOLOGY AND TOURISM*). The economic potential of tourism is often evident in the motivations for seeking World Heritage designation. However, the pressures on World Heritage properties can be exacerbated by poorly managed tourism, which can also have the effect of displacing local people and/or their traditions and livelihoods. Managing the development of tourism infrastructure and the flows of benefits is therefore central for many World Heritage properties.

The World Heritage system establishes what has been termed a “three-legged stool”—States Parties, the World Heritage Committee, and Advisory Bodies—and its stability relies on each of these structural components to function effectively. Today, this metaphor is complicated by perceptions of increased politicization of decisions and opportunities for cultural diplomacy. The centrality of the state and the role of experts create obvious points of potential tension for local communities because applying OUV can filter out important local associations and traditions. The requirements for community involvement and consent are only generally described; and reports from media, professional organizations, and academic studies contain many cases where the outcomes of World Heritage for local people have been confusing or detrimental to their livelihoods, cultural practices, or self-determination. Yet there are other examples of proposals developed by communities themselves in “bottom-up” processes, suggesting promising possibilities for the future designation of World Heritage Sites.

Adobe

LUIS GUERRERO

Universidad Autónoma Metropolitana–Xochimilco,
Mexico

FRANCISCO UVIÑA

University of New Mexico, USA

The word adobe is described as a sun-dried mud brick. The use of these blocks to construct floors, walls, arches, and vaults is called adobe construction system. Adobe has been highly valued by many societies around the world because of its bioclimatic efficiency in cold and hot, arid, and humid regions.

The name adobe has its origins in the Spanish language and derives from the Arabic term “ottob” which means brick. Even though the word employed was documented in Spain in the twelfth century, it was not published in a dictionary until 1726 (Caro 1998).

However, the use of this construction system logically precedes by several thousand years the spread of its Castilian name. In the Middle East, archaeological evidence of its use has been found dating back to 8000 BC (Houben and Guillard 2001). The extensive diffusion of this building technique lies in the simplicity of mud brick manufacturing, storage, and construction. The survival of this traditional knowledge constitutes a fundamental source of information to be applied in contemporary sustainable construction.

The expression “adobe” is used erroneously as “mud” or unbaked earthen building systems. Previous research related to the origin and development of adobe presents multiple loopholes, mistakes and inconsistencies. Some of these derive from the names given to construction elements and typologies (Bardou and Arzoumanian 1981).

Adobe buildings consist of an elaboration of earth blocks that are shaped with adequate dimensions for ease of sun drying transport, and stacking. These units are stacked and laid in mud mortar in alternating course work, similar to the

technique used in masonry to place bricks or dressed stone.

Adobes have different forms and dimensions, ranging from hand-shaped amorphous types to those made with a shaped rigid mold. In some locations, it is possible to follow the evolution and the morphology of early adobes beginning with those presenting flat-convex forms obtained from the placement of mud balls on the ground, up to parallelepiped blocks with an elongated rectangular shape that are most common around the world.

Sphere-like, cylinder, conic, trapezoidal shape adobes exist, as well as special units designed for ornamentation purposes. Baskets or boxes made of reed were used to manufacture blocks. The rectangular shaped adobes made with wood molds constitute the peak of the adobe technology and evolution of the geometric form, remaining unaltered for thousands of years, as can be seen today. The geometry of these rectangular forms with a thickness equivalent to approximately one quarter of its length allows for different types of coursing and permits a rapid drying of the units that can be stacked on edge so its hardening becomes homogeneous (Fathy 1973).

The logic of the construction system is dictated by a careful size and handling of the units, as well as its production. This guarantees quality control in coursing and building profiles. Even though adobes of a larger size allow for less units per course, this could delay the construction due to the effort needed to mobilize heavier blocks. This is why, even without an existing “international standard,” the rectangular adobes in most of the world have dimensions between 16 and 32 inches in length, 8 and 16 inches in width, and 4 and 6 inches in thickness so that the total weight could be handled by one builder.

The soil to make adobe is extracted from the earth strata below the layer known as the “organic layer.” Most societies in the past learned how to modify their local natural soil characteristics and mixing earths.

The soil utilized to manufacture adobes requires the plasticity of clay that gives consistency

to the mix for correct modeling. Therefore, the production starts with the dampening of the soil at a large scale for the correct breakdown of all clods of earth.

High moisture content in the mud and plasticity in its clays produce the risk of shrinkage, deformation, or cracking during drying. These alterations can cause problems in the transfer of loads and, above all, may allow infiltration of parasitic flora or fauna. Furthermore, the presence of fractures allows moisture penetration, the main cause of deterioration.

For this reason, most of the ancestral traditions in the adobe production consider the incorporation of added material that prevent shrinkage of mud mixture during the drying process, and improve structural tolerance and diminish vulnerability to moisture. These components are generically known as “stabilizers” and are greatly diverse, which would logically depend on available natural resources in each site.

Among the many stabilizers commonly used are cactus mucilage, bark extractions, soluble carbohydrates, lime, shredded straw, pine needles, horse or cow manure, as well as vegetal and animal fats or asphalt emulsions (Guerrero 2007, 188).

The wet and stabilized soil is mixed with available tools and techniques. Historically, the means used for mixing the mud have ranged from bare feet and hands to the use of horses and cattle hooves or garden tools. Traditionally, it was accustomed to allow the mix to sit for one or several days to improve the distribution of materials followed by molding the units.

The manufacturing process begins with the spreading of sand over the work site where a previously moistened wood mold or formwork is set. The mud mix is poured into the formwork and pushed into place with hands or feet, perfectly spreading it into the corners. Once the formwork is full, the top is screed flat and the adobe mold slowly lifted to prevent slumping along the edges.

The blocks are exposed to the air to allow homogeneous drying. When they reach the necessary strength for handling, they are turned on edge in order to properly dry for a period of 3 to 4 days, so that afterwards it is carefully stacked to allow proper ventilation between them. Drying time is fundamental to guarantee the proper

strength of all its constructive units. If an adobe is not completely dry, it is possible that the building can suffer deformations, weakening the structure as a whole.

Even though some texts mention that it “requires around three weeks” for an adobe to obtain its adequate strength (Prieto 1987, 80), Vitruvius (1914, 42–3) prescribed 2,000 years ago that adobes “should be made in spring or autumn, so that they may dry uniformly. [...] Bricks will be most serviceable if made two years before using; for they cannot dry thoroughly in less time. [...] This is so true that at Utica in constructing walls they use brick only if it is dry and made five years previously, and approved as such by the authority of a magistrate.”

The most common wall facing in one or two-story buildings is usually made with the width of the adobes oriented along the coursing of the wall. However, the facing varies considerably according to the proportions of the adobes, the wall height, the roof loads, as well as the regional seismic conditions.

The care for its course lapping is fundamental when comparatively describing a more fragile masonry system needing an adequate distribution of loads. Likewise, special attention should take place at corners and transverse wall connections, which are most vulnerable in buildings. The mortar has always been executed with a mix similar to the adobes and prior process of repose, to allow a proper moistening of its clay.

The adobe construction as we presently know it has evolved over millennia and has manifested throughout developed, organized, and diverse territories around the world. Adobe walls were used in buildings at Chan Chan in Perú, Djenné in Mali, and Bam in Iran. However, adobes were used to elevate mounds and fortresses, even to construct massive plinths. In these cases, it is typical for visitors to archaeological sites to not recognize its presence since the structures were veneered with stone or plastered for protection (Cornerstones Community Partnerships 2006).

Due to the vulnerability of adobe to moisture, these building systems normally require constructing over foundations—mainly stone footing—the implementation of roof overhangs

to prevent the impact of rain, and especially the application of plasters.

This adobe building system facilitated the development of numerous earth plaster types that were often enriched with moisture protective materials and paint. These plaster applications were used to implement high and low reliefs with a variety of designs that added to the rich value of this architecture.

Adobe was used to build arches, vaults, and domes. These architectural elements were common in areas with a limited amount of wood and lower levels of precipitation.

Adobe is one of the most common construction systems in the world, but has received little attention by investigators, preservationists, and professional contractors. Sometimes inhabitants of adobe buildings consider them unsanitary, unsafe, and associated with poverty because they ignore their historical and ecological values.

This is why the implementation of studies to examine the value and limits of adobe as a building system is fundamental to seek its preservation, and improvement, and to integrate present and future sustainable design.

This process opens various routes for the development of scientific research and practical work. These studies may include the physical analysis of old adobes, the chemical determination of stabilizing substances, crystallography, petrography, granulometry, chromatography, X-ray diffraction analysis, scanning electron microscopy (SEM), comparison of deterioration processes, evaluation of conservation alternatives used in different sites, typological documentation of building systems, among many others.

It is essential to rescue, value, and reuse this traditional architecture knowledge in order to apply it to new building design. However, this acquisition of knowledge might not be restricted to form or material composition, but requires the understanding of its architecture as a system (Guerrero 2007).

Additionally, it is necessary to identify and preserve the intangible heritage that constitutes the traditional knowledge seen today. It is essential to protect the materiality of historic adobe buildings in order to preserve their link with society (Guerrero and Uviña 2004).

Finally, it is crucial to disseminate adobe building knowledge among inhabitants, students,

architects, engineers, and government agencies. Furthermore, it is important to investigate the economic and ecological qualities of adobe architecture, thus allowing for the continuation of heritage architecture along with modern sustainable design.

Ancient Mortars and Plasters

DOMENICO MIRIELLO

University of Calabria, Italy

Ancient mortars are mixtures made of inorganic binders, aggregates, water, and sometimes organic or inorganic additives that gave the mixture the desired workability and enabled the mortar to set and harden.

Ancient plasters are wall, roof, or floor coverings made up of one or more layers of mortar applied in a single construction phase.

Mortars can be divided into two macrotypologies: aerial mortars and hydraulic mortars. Aerial mortars set and harden in aerial conditions, while hydraulic mortars set and harden even when they are totally or partially immersed in water.

The raw materials used for making the inorganic binders of ancient mortars are carbonate rocks (limestone, marly limestone, dolomite, travertine), evaporite (gypsum), and metamorphic rocks (marble). Various types of mortars can be produced by mixing calcined raw materials with aggregates and water—for example aerial and hydraulic lime mortars, magnesium lime mortars, and gypsum mortars (both with aerial features).

The birth of pyrotechnology has greatly contributed to the diffusion and improvement of the production technology of mortars and plasters. It is probable that gypsum-based mortars go back further than lime-based mortars, because they can be produced at much lower temperatures (Elsen, van Balen, and Mertens 2012).

Evidence of the use of lime dates back to 11,000 BC and comes from the cave of Hayonim in Northern Israel (Vidale 2007; Artioli 2010). The most ancient mortar known to us today is probably the mortar that was used for making the floors in Yaftah (Southern Galilee) around 7000 BC (Bensted 1997; Pecchioni, Fratini, and Cantisani 2008). In the seventh and in the eighth millennium BC the production of lime and

gypsum plaster was quite complex, as evidenced by the building statuary and manufacture of containers in the Ancient Near East (Vidale 2007; Artioli 2010).

Many mortars that have been preserved until today have hydraulic properties. The hydraulicity of the binder can be due to the use, in the lime production process (calcination of the raw materials), of impure limestones with high content of silicon, aluminum, and iron (marls or marly limestones). In this way it is possible to obtain natural hydraulic lime.

Another way to obtain artificial hydraulic lime from aerial lime is by adding natural and artificial pozzolanic materials to the mixture. Natural pozzolanic materials are generally made of highly alkaline volcanic materials. The adjective “pozzolanic” came from “pozzolan,” a highly alkaline volcanic ash that the Romans used extensively between 300 BC and AD 200. The pozzolan (Figure 1a) was quarried from the Campi Flegrei area to the northwest of Naples, where the city of Pozzuoli is located (Artioli 2010). The most widely used artificial pozzolanic material in ancient times was crushed pottery mixed with brick fragments (*cocciopesto*), which was sometimes finely powdered (Figure 1b). Natural and artificial pozzolanic materials react with slaked lime, thus making the mixtures hydraulic and causing the formation of low crystallinity C-S-H phases (calcium–silicate–hydrate). Pozzolan was used for the construction of Minoan tanks in 1300 BC, as documented in the literature, while the Phoenicians used *cocciopesto* in the tenth century BC for coating tanks (Amoroso 2002).

Most often crushed pottery mixed with lime was used for the realization of hydraulic constructions like baths, tanks, and aqueducts. However, there are cases where crushed pottery and brick fragments were used to prepare mortars for structures that did not contain water, such as Roman floors and sidewalks (e.g., at Pompei). Crushed pottery and bricks were used also in joint mortars of ancient buildings; the joint mortars of Hagia Sophia in Istanbul, one of the most important buildings of antiquity, are an important example.

Figure 1 Microphoto of various types of pozzolanic materials under crossed polars: (a) Pozzolan fragment in the mortar from Casa di Pansa at the archaeological site of Pompei; (b) *cocciopesto* in the mortar from Casa di Pansa at the archaeological site of Pompei; (c) metallurgic slag in the mortar from the S. Niccolò archaeological site in Montieri, Tuscany. The sample was obtained from the Medieval Archaeology Group at Siena University, from a project directed by Giovanna Bianchi.

The crushed brick and lime of Hagia Sophia was classified as an advanced cement-based composite, which allowed the structure to survive numerous earthquakes (Moropoulou et al. 2006).

The Romans used natural pozzolan extensively in the production of joint mortars in different parts of the empire; but they were not alone. Populations in Mesoamerica, for instance the Mexicas, used natural pozzolanic materials in the production of lime plaster. The lime plasters from Templo Mayor (the Great Temple), the main pyramid of Tenochtitlan in Mexico, are a case in point. In Mexico the volcanic pozzolanic fragments are known as *tezontle* and show a variable color, which can go from dark grey to red.

In addition to pozzolan and *cocciopesto*, other natural and artificial materials were used in ancient times for producing hydraulic mortars: diatomaceous earth, metallurgic slags (see Figure 1c), kaolin, and opal-A. The medieval hydraulic mortars found in the tower of Pisa in Tuscany were produced by mixing slaked lime with diatomaceous earth, which was probably quarried at Mt. Amiata (Franzini et al. 2000), approximately 180 kilometers to the south of Pisa.

Various types of organic raw material mixed with lime were used to produce mortars and plasters in antiquity. The practice of adding charcoal to lime is described in Pliny's *Natural History* (Book 36, ch. 63). Vegetal charcoal (Figure 2a) was used as an aggregate in the plasters of the large early Christian baptismal font found during the excavations carried out at the Church of Son Peretò in Mallorca.

In Mesoamerica, evidence was found of the use organic materials such as mucilage of nopal,

a particular type of Mexican cactus, in the production of lime plasters. In ancient China, sticky rice and lime were mixed together to make mortars and plasters. In the archaeological site of Kyme in Turkey it was found that vegetable fibers (Figure 2b) were used for making lime plasters from the fifth to the seventh century AD. The scientific debate regarding the function of the organic substances that were added to the mortars and plasters in antiquity is still open.

Out of all ancient societies, the Romans were probably the most highly skilled in the production of mortars and plasters, and by reading Vitruvius' *De architectura* and Pliny's *Natural History* we can clearly see how much importance they accorded to the type of the raw materials used for making mortars and plasters and to their preparation.

Pliny stated that lime putty should be left to age for at least three years in order to make a good lime binder. The slow aging of lime putty reduces the size of the portlandite crystals ($\text{Ca}(\text{OH})_2$), thus improving the characteristics of the mortars and plasters.

Vitruvius, in Book 7 of his treatise on architecture, speaks of seven layers of mortar in the preparation of plaster. At the house of Longus on the archaeological site of Pompei, there is an plaster, approximately 5 cm thick, made of six layers of mortar; despite being almost 2,000 years old, this plaster is very well preserved and solidly attached to the wall. The first five layers are made of a mixture of lime and pozzolan, with the grain size decreasing from inside to outside; the last layer is made of a mixture of lime and finely crushed marble powder.

Figure 2 (a) Microphoto under parallel polars of charcoal used as aggregate in the lime plaster from the large early Christian baptismal basin in Son Peretò (Mallorca, Spain). The sample was obtained from the Equip de Recerca Arqueològica i Arqueomètrica de la Universitat de Barcelona (ERAAUB), directed by Miguel Àngel Cau Ontiveros; (b) Microphoto under parallel polars of a vegetable fiber in lime plaster of the fifth–seventh centuries AD from the archaeological site of Kyme in Turkey; the sample was obtained from Antonio Lamarca, the director of the archaeological mission in Kyme.

If the Romans often mixed lime with other raw materials, to various proportions, to make all the layers of the plaster, other societies prepared the first layer with different raw materials, as we can see by observing lime plasters from the ancient Mexican city of Teotihuacan. In Teotihuacan, the floor of the main courtyard at Teopancazco was made of two superimposed layers of plaster (Barba et al. 2009): the inner preparatory layer was made of beaten earth mixed with crushed volcanic rocks without lime; this layer was known locally as *firme*. The external layer, which was approximately 2–3 mm thick, was made by mixing lime with volcanic glass shards and was known locally as *enlucido*.

Mortars and plasters are considered to be artificial stone materials similar to sandstone, which is a sedimentary rock. The mortars preserve the technological imprint of the workers who produced them. A detailed compositional study of the mortars can provide valuable insight into the technological know-how of a certain historical period. It is likely that mortars with similar compositional characteristics belong to the same construction phase. For this reason, mortars can be used to solve issues such as the individuation of the constructive phases of an ancient building. The most suitable mortars for establishing the construction phases of an ancient building are

“joint mortars,” which are wall mortars that link two bricks or two building blocks.

Archaeometric studies on mortars, focused at the recognition of constructive phases, depend on the quality of the sampling in situ. The samples should be selected on the basis of preexisting archaeological hypotheses. The number of samples must be statistically representative of the compositional variability of the mortars: this is because the mortars are heterogeneous materials and the size of the clasts that form the aggregate can range greatly.

The best approach for understanding the secrets of the ancient mortars and plasters is the multianalytical approach. The analytical techniques most widely used for studying the composition of mortars and plasters are the same techniques that are generally used for the compositional characterization of rocks: polarized light microscopy (PLM), X-ray fluorescence (XRF), X-ray powder diffraction (XRPD), and scanning electron microscopy with X-ray microanalysis (SEM–EDS). Specific analytical methodologies can be used together with the above-mentioned techniques for carrying out in-depth studies on the mineralogical composition of the aggregate and the binder and for determining the provenance of the raw materials used for their production: laser ablation inductively coupled with plasma mass spectrometry (LA–ICP–MS),

micro-Raman spectroscopy (MRS), transmission electron microscopy (TEM), Fourier transform infrared spectroscopy (FTIR), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA) and image analysis performed on thin section.

However, PLM is deemed superior to other techniques and is essential for studying the petrographic and micromorphological characteristics of mortars; moreover, PLM is required to program, optimize, and better interpret all of the analyses carried out on the samples. Two mortars may have the same chemical and mineralogical composition and a different petrographic composition at the same time; only by performing PLM on thin sections can we avoid making this type of mistake.

A good analytical step-by-step approach for studying ancient mortars and plasters consists of:

1. macroscopic observation of the mortars during and after the sampling;
2. a preliminary study of the samples in thin sections with transmitted PLM and XRPD analysis of the bulk sample;
3. recognition of the geochemical groups using the cluster analysis on XRF data; and
4. the validation of the geochemical groups with PLM on thin sections and the recognition of the various construction phases.

Subsequently the binder can be studied by:

1. identifying the lime lumps in thin sections with PLM;
2. analyzing the lime lumps and the binder through SEM-EDS analysis and LA-ICP-MS;
3. studying the C-S-H phases of the binder with the TEM analysis.

The study of the binder in the ancient mortars, linked to the evaluation of their degree of hydraulicity, is a complex problem. The complexity arises from the difficulty to detect and quantify the hydraulic compounds in the binder fraction. If their crystallinity is high, it is possible to use X-ray powder diffraction (XRPD) to detect the C-S-H phases; on the other hand, it is possible to use thermogravimetric analysis (TGA) to make a distinction between hygroscopic water,

water from hydrated salts, and the loss of the water bound to hydraulic compounds (Elsen, van Balen, and Mertens 2012). Another promising method for obtaining information about the distribution of the hydraulic compounds in the binder fraction is micro-FTIR imaging, coupled with attenuated total reflectance (Diekamp et al. 2012). The method is based on the study of the reaction rims around the pozzolanic materials; in particular, it allows identification of the group of bands between 900 and $1,120\text{ cm}^{-1}$, which is assigned to Si-O stretching vibrations indicating C-S-H phases. The hydraulicity of the binder of mortars and plasters can also be highlighted by studying the Si/Ca ratios in the reaction rim through scanning electron microscopy with X-ray microanalysis (SEM-EDS).

In recent years, various techniques such as optically stimulated luminescence (OSL) and radiocarbon (^{14}C) have been used for the dating of ancient mortars. Although satisfying results have been obtained through these techniques, they have not yet been fully consolidated for dating mortars and plasters. Not all ancient mortars and plasters can be dated by means of radiocarbon (^{14}C) and OSL; the correct application of these techniques depends on mineralogical composition and on the extent of decay. Moreover, in order to apply the radiocarbon (^{14}C) to the binder and lime lumps contained in the mortars, it is essential to study the mortar with an optical microscope under transmitted polarized light and Fourier transform infrared spectroscopy (FTIR), to determine the various types of calcium carbonate and to separate them from the calcite formed during the carbonation process of the lime; in fact, in addition to lumps and binders, mortars may contain different types of calcium carbonate: secondary calcite crystals that form within porosity; fragments of carbonate rocks contained in the sands used as aggregate; or even fragments of mortar older than the one to be dated, deriving from secondary raw materials that are reused as aggregates in new mixtures.

It is seldom possible to identify and extract traces of charcoal from ancient mortars and plaster, which remained as residues of the combustible material used during the calcination of the limestones. With a sufficient amount of

charcoal it is possible to date the mortars using the radiocarbon (^{14}C) method.

In most cases mortars and plasters are made with raw materials that can be found in close proximity to the architectural structure to which they belong. However, this is not always the case, and the provenance studies carried out on raw materials used for producing mortars can sometimes give very interesting results. The raw materials used for preparing mortars are aggregates and carbonate rocks used for producing lime. In recent years, good results have been obtained with laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), which is used for establishing the provenance of ancient mortars and plasters. This technique has been successfully applied in determining the provenance of the aggregate and limestones used for making the plasters that covered the floor of the main courtyard at Teopancazco (Barba et al. 2009), at the archaeological site of Teotihuacan. The lime lumps that form during the slaking of the lime preserved the chemical composition of limestones with which they were produced. LA-ICP-MS analyses were performed simultaneously on the lime lumps and on the probable quarries of the limestone in order to determine the major elements and the trace elements. The results showed that Tula (85 km west of Teotihuacan) was the only possible source of the limestone used for making the Teopancazco courtyard plaster. The same approach was applied to determine the provenance of the volcanic aggregate (glass shards) found in the plaster of the Teopancazco courtyard and determined that the glass shards came from the Altotonga magmatic system, located 180 km east of Teotihuacan. These results showed that the place of provenance of the raw materials of the mortars and plasters was quite a long way from the archaeological area, thus enabling archaeologists to trace ancient trade routes.

Another very important aspect in the study of ancient mortars and plasters concerns the compatibility of the repair mortars used for restoring an ancient building. A repair mortar is generally considered to be fit for purpose when it is aesthetically, chemically, mineralogically, mechanically, and physically compatible with the substrate on which it is to be applied. At the end on the nineteenth century and throughout

most of the twentieth, Portland cement was widely used for restoring ancient monuments, yet many compatibility issues have arisen between ancient lime mortars and Portland cement over the years. The best way of making mortars that are compatible with ancient ones would be to find all of the original raw materials used in the mixture, which could then be used to produce new mortar. It is therefore essential to carry out in-depth analyses on the ancient mortars and plasters used for construction before restoration.

Bones and Ivory

SIAN L. TILEY-NEL

University of Pretoria, South Africa

Bone and ivory are the predominant materials of animal origin to survive within the archaeological environment. They are an organic source of information that can elucidate our understanding of past animal species, diets, diseases, aspects of domestication, trade, materials, and technologies, as well as the utilization of raw materials, but more importantly the relationship between animals and people of the past. Since bone and ivory are derived from animal skeletal remains, they form part of the natural cycle of decay as organic material, and are therefore unlikely to survive burial intact, in comparison to inorganic remains such as lithics (stone), metals, and ceramics. Usually, archaeological bone and ivory remains are amorphous, without discernible shape due to their fragile and fragmentary state. Specialist knowledge of modified or worked bone and ivory, in particular, is fairly limited, as research tends to approach each material differently, despite their similar chemical composition and signatures. Any research approach should, however, investigate archaeological bone and ivory based on an understanding and appreciation of their composition as raw material (Tiley-Nel and Antonites 2015).

Bone is a mineralized connective tissue that forms the skeletal support of vertebrate animals, whereas ivory is the unusually large projecting teeth or tusks of animals. Other protein-based organics include shell, horn, and antler, leather or hide, and hippopotamus and warthog ivory. Collectively, these are also referred to as osseous materials, which are the hard body parts of animals, including bone, antler, teeth, ivory, turtle shell, hooves, and horns (O'Conner 1987).

Animal bone is essentially the skeletal material (bony elements) or anatomical part of a mammal's internal skeleton. Bone is a mineralized connective tissue primarily comprised of two

main elements: organic matrix (collagen-protein) and inorganic mineral (hydroxyapatite). The mineral part of the bone is comprised mostly of calcium and phosphorus, with small amounts of fluorine, sodium, and magnesium. The main carbon-based portion of bone is composed of a protein called ossein. Bone has two major types of structures, namely the cancellous bone and the more compact or cortical bone. The light cancellous or spongy tissues are found within the interior of bones, and the heavier, denser, compact tissues are found on the outside, and in the long shafts of long bones. Compact bone, which makes up the shafts of limb bones (long bones), tends to have a laminated structure on their external surface. Since compact bone is usually tubular, it is frequently used for cylindrical artifacts such as handles and bone tools, which are cut from strips of compact bone. Despite its compact appearance, bone is remarkably porous on a very fine scale, which helps to hold the bone marrow or soft tissue that produces red blood cells. The porosity of bone is likewise due to the make-up of canals that store the nerves and blood vessels (O'Conner 1987; Cronyn 1990).

Ivory, as distinguished from bone, includes tusks and the large projecting teeth of animals. Although the term "ivory" is traditionally applied to the tusks of elephants (the order of Proboscideans), it includes teeth and tusks from mammoth, walrus, killer whale, sperm whale, narwhal, hippopotamus, and several pig species such as warthog, boar, and bush pig. It is relatively easy to distinguish among the various animal ivories by the characteristic geometric growth and the layering of organic and inorganic matter according to well-defined patterns (Espinoza and Mann 1992, 10). Ivory is primarily composed of another form of bone called dentine, which in turn is coated with enamel and cementum. The organic component makes up about 20 percent of living dentine, with about 70 percent mineral component and the rest water. The dentine contains a microscopic structure called dentinal tubules, which form long sheets referred to as micro laminae (Locke 2008). These laminate or lamella are sometimes called the "grain" of

DOI: 10.1002/9781119188230.saseas0067

ivory and it is prone to extreme warping and delamination, a signature characteristic of ivory, because when buried it becomes brittle as the laminate or growth layers degrade over time (Tiley-Nel and Antonites 2015, 16–18).

Ivory is also one of the hardest organic materials, but because it has poor elastic properties, any area that is under pressure is subject to the formation of cracks or material loss. In transverse section, elephant ivory exhibits a unique pattern of intersecting lines, which form small diamond-shaped areas visible to the naked eye. This distinctive structure characterized by the intersecting lines is also known as the so-called Schreger pattern (Locke 2008). The intersections of Schreger lines form angles which appear in two forms: concave angles and convex angles. This chequered or cross-hatch pattern aids in positive identification of elephant ivory, as it can be seen by the unaided eye on transverse profiles or by discoloration of the surface (Tiley-Nel and Antonites 2015). The significance of the Schreger pattern has important taxonomic implications, as this exclusive feature is highly important in the identity of true ivory and is singularly characteristic of most proboscidean ivory (Espinoza and Mann 1992).

Both bone and ivory have complex compositions comprising two components: the inorganic mineral (hydroxyapatite) and the organic matrix (collagen-protein). It is the inorganic component that provides strength and rigidity and the organic component that provides the capacity for growth and repair. The inorganic component consists of mineral hydroxyapatite (an insoluble salt of calcium and phosphorus or calcium phosphate) and the organic component consists of mainly collagen and small quantities of lipids. Both the inorganic and organic component of bone and ivory also contain water, some of which is lost over time, thus leading to hardening. These elements have very different functions and properties, which, in combination, allow bone and ivory to be hard and flexible, so as a result excavated bone and ivory are sometimes visually indistinguishable and are therefore used as an ideal raw material for the manufacture of artifacts (Py-Daniel 2014).

Worked bone and ivory have the potential to inform archaeological interpretations about the production of raw materials into artifacts. Therefore, an important constituent of modified

bone and ivory into artifacts is the proper identification of the raw materials chosen to make them. The surface structure and morphology of modified animal bone and ivory can lead to greater accuracy in identification (Espinoza and Mann 1992). Observations of shape, color, hardness, texture, deterioration, signs of damage, and other physical qualities relate to the nature of the raw material and to techniques of manufacture. Furthermore, such information is critical to determine the specialized conservation needs of bone and ivory and to make informed choices about appropriate analytical techniques because bone and ivory are often suitable samples for a number of archaeometric methods such as radiocarbon dating, trace use-wear analysis, isotopic analysis, and organic residue analysis (see ORGANIC RESIDUE ANALYSIS). Bioarchaeology (see BIOARCHAEOLOGY) specifically investigates the survival of biomolecules on animal tissues, such as protein focusing on degraded collagen and albumin. Furthermore, it is well known that proteins survive longer than DNA, and, in recent studies, scientific techniques such as the analysis of ancient DNA (aDNA) and proteomics or the study of proteins aid archaeological knowledge of the longevity of protein survival in ancient bone.

Proper identification and investigation of the raw material can reveal potential evidence, such as the nature of the material, and its physical properties, structure, and composition. However, many changes similarly occur to archaeological bone and ivory, especially when exposed to adverse environmental conditions. These variations can alter the physical structure and chemical composition, and lead to further changes such as damage and deterioration. The processes that change the nature of bone and ivory during burial and how these processes are determined environmentally are often referred to as diagenesis (see DIAGENESIS OF BONE). Due to their inherent fragile nature, there are numerous types of pre-burial, burial, and post-excavation changes to archaeological bone and ivory in particular. It is therefore important to distinguish between chemical and structural damage resulting in surface modifications on bone and ivory, which is fundamentally important to zooarchaeology (see ZOOARCHAEOLOGY) as well as to the study of the conservation of organic materials. Preservation of bone and ivory varies considerably, because

they are made up of both organic and inorganic constituents, which are preserved at opposing pH; that is, the measure of alkalinity or acidity of the surrounding environment essentially determines the extent of preservation (Cronyn 1990).

Buried bone and ivory are modified by and weathered from physical and chemical processes, the result of which can be cracking, splitting, exfoliation, disintegration, delamination, abrasion, decomposition, or degradation. Ivory is particularly reactive to its environment and is very sensitive to any changes in relative humidity, moisture, and temperature. This causes further delamination and color changes, such as lightening when exposed to light or darkening as a “patina” which may also be evident as a result of the natural aging process of ivory’s organic constituents. The slightest temperature variance in the environment and exposure to moisture will cause damage in both ivory and bone (Cronyn 1990). This is because bone and ivory are both anisotropic and hygroscopic; that is, they have different physical properties in each direction, meaning that moisture changes can exert stress or tension on their physical structure, resulting in damage and deterioration (Lafontaine and Wood 1982).

Although bone and ivory are complex in structure and morphology, but have similar chemical signature compositions, being composed of both organic and inorganic components, they are preserved at opposing pH (potential of hydrogen). Therefore, pH is essentially one of the largest influences on the loss of these organic materials. The inorganic hydroxyapatite deteriorates in acidic environments, while the collagen (organic) deteriorates in alkaline environments. In acidic conditions, the inorganic components dissolve, leaving ivory to shrink when it dries out, causing warping, delamination, and material loss, whereas acidic conditions will result in the leaching of bone minerals, causing bone to lose strength and rigidity as it becomes friable (Cronyn 1990, 277).

By means of archaeological investigation, proper museum conservation, curation, and collections management practices enable studies of bone and ivory as raw osseous materials. Such practices allow for closer examination of the traces left by animals and human and natural modifications which can elucidate valuable research information about the manufacture, use, and discarding of modified bone and ivory.

Also an in-depth understanding of the structure, composition, and constituents of bone and ivory can be fundamental to the comprehension of excavated organics, as well as understanding how and why they survive the archaeological record.

Cements, Mortars, Binders

CÉLINE GILLOT

Université de Montréal, Canada

ARNAUD COUTELAS

Arkemine, France

Overview

Cements, mortars, and binders are materials with adhesive and cohesive properties primarily used for construction purposes. They form an important class of building materials and have been employed to create, protect, or decorate buildings and engineering works for at least 10,000 years. Over the last decades, as interest in ancient building materials and practices has grown, a substantial number of investigations have been devoted to the analysis of samples taken from old masonry structures, finishing coatings, and ornamental elements. Typically, the materials sampled have been analyzed for (1) determining their composition and properties; (2) deriving information about their production and its organization; (3) assessing their age; or (4) understanding the causes of their degradation and evaluating repair and conservation strategies. A variety of analytical techniques have been used, and several standard protocols have been proposed to guide mortar characterization.

Mortar terminology

Ancient mortars have attracted the attention of many specialists from different fields, not only from archaeology, history, and conservation science, but also from architecture, civil engineering, and materials science. Many terms have been used to describe them; and the lack of a common vocabulary across disciplines has led to inconsistency and confusion in terminology. Different materials have been designated by the same

term and different terms have been applied to the same material. The terms “cement,” “mortar,” and “binder” are no exception in this regard and have been adopted as both generic and specific names for various materials. The terminology proposed here follows the most common usage and each of these three terms is assigned to a specific material.

Mortars may be defined as composite materials obtained by adding water to a mixture made up of two basic components, a binder and a filler. The binder is the substance that gives consistency and adhesiveness to the mortar. It forms a continuous matrix and plays an essential role in the setting process. While it is not impossible to use a binding substance alone, in practice it is often necessary to add a filler, that is, a material that gives it bulk, strength, and stiffness. Usually this material consists of finely divided mineral matter, or of aggregates. Additional components eventually incorporated into the mix to further enhance its performance or to achieve special properties are usually regarded as additives. Water is used to make the mixture plastic and workable long enough for it to be properly placed and shaped. Once in place, the paste progressively hardens into a solid and relatively permanent material as the binder sets.

It is to be noted that the terms “binder” and “cement” are frequently used interchangeably. However, in its more restricted sense, “cement” only refers to a specific type of binder, produced with modern equipment and technologies. Moreover, it should also be specified that mortar and concrete are similar in composition. Concrete is also composed of water, a binder, and a filler. It may, however, be regarded as a distinct material, since it contains both fine and coarse aggregates. The use of sand, gravel, or crushed stone as aggregates significantly affects the physical and mechanical properties of the final product. Unlike mortar, concrete has no binding force, but can be used alone and is strong enough to bear heavy loads.

Applications

Many different kinds of buildings constructed with mortar still survive in different parts of the world. They attest not only to the widespread use of mortar, from prehistory up to the present day, but also to the great variety of mortar types. Archaeological and historical evidence suggests that the selection of a particular mortar was determined by several factors, including the availability and cost of raw materials, local building practices, and mortar applications. As it is extremely versatile and easy to produce in various forms, mortar has fulfilled a wide range of functions. Briefly, it may have served as (1) a bonding material (for bedding, jointing, and pointing stones and bricks, or for infilling masonry structures); (2) a finishing material (for internal plastering, external rendering, flooring, waterproofing, and sealing); or (3) a decorative material (for casting, molding, modeling, and fixing or supporting architectural ornaments).

Materials and production methods

Before the industrial revolution, mortars were prepared using raw materials essentially derived from locally available resources. The most common binders were mud, gypsum, and lime, or combinations of these substances. Organic binders such as bitumen, natural oils, waxes, and resins were also used, but to a lesser extent. Over the course of the eighteenth and nineteenth centuries, with the emergence of cement-based products, the use of these traditional binders declined. Natural, then artificial cements became the predominant types of binder in use.

Mud-based mortars

The most basic binder used to produce mortar is mud, or earthen material. Earth is available almost everywhere and can easily be made into a malleable paste through the addition of water. Given the variability of soil types from place to place, the properties of the material obtained can differ widely. Generally, however, the most suitable soils are characterized by a homogeneous particle size distribution and by a moderate

proportion of clay minerals. The clay content is especially important, since it determines the cohesive strength and the plastic behavior of wetted earth, as well as its drying shrinkage rate. If the proportion of clay minerals is too low, the mud will lack binding force; if it is too high, the mud will tend to crack on drying. Unlike gypsum and lime binders, mud simply sets and solidifies by desiccation, without undergoing chemical change. Although some soils may produce relatively good mortars without further modification, mud-based mixes are traditionally improved by adding mineral aggregates and fibrous matter. The addition of copious quantities of chopped straw or other natural fibers helps increase strength, control shrinkage, and reduce cracking. Mud may also be combined with lime or other additives in order to prevent the formation of cracks and provide better water resistance and durability.

The resilience of mud and the tendency of earthen materials to promptly soften and crumble if unmaintained or exposed to natural elements partly explain why ancient mud mortars have left rather scant and poorly recognizable archaeological evidence by comparison to other bonding and plastering materials (see DETERIORATION OF EARTHEN BUILDING MATERIALS). Pieces of accidentally burned mortars and plasters or exceptionally well-preserved remains show, nevertheless, that this type of mortar has been extensively used, at least since Neolithic times and in nearly all preindustrial societies. Moreover, although its popularity has progressively decreased in the recent past, it still continues to be a material of choice in various regions of the world.

Gypsum- and lime-based mortars

Gypsum and lime are among the earliest examples of artificial materials whose production depends on chemical modification by fire. The discovery that, once burned and ground, certain rocks can be mixed with water to produce a paste that may be used in the same way as mud seems to be intimately connected with the advent of pyrotechnology, some 10,000 years ago. The process by which these rocks are converted into binding materials is, however, more complex than preparing the mud and involves various chemical reactions. As it starts with the disintegration of the

raw material and ends with its reintegration, this multistep process is often referred to as a “cycle.”

The gypsum cycle can be divided into two major steps: the calcination and the hydration of gypsum minerals. In nature, such minerals are typically found in gypsum rocks, in the form of calcium sulfate dihydrate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$). When subjected to fire, gypsum loses its combined water. The dissociation process starts at approximately 70°C and, at $100\text{--}200^\circ\text{C}$, gypsum turns into hemihydrate ($\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$: bassanite). Further heating removes all the water and leaves anhydrous calcium sulfate (CaSO_4 : anhydrite). It should be mentioned that naturally occurring anhydrite rock can also be used for gypsum production without the need to calcine it. The dehydration of calcium sulfate, either partial or total, is simply reversed through the addition of water. When powdered burnt gypsum is mixed with water to form a soft paste or a slurry, hemihydrate and anhydrous sulfate recombine with water molecules, recrystallize, and revert to a dihydrate state. Consequently, the starting and the end products are chemically similar. Powdered bassanite, also known as “plaster of Paris,” quickly reacts with water and is converted into a mass of tiny interlocking crystals that allow the mortar to cohere and set into a rigid, new stone-like material. Anhydrite is less reactive. It takes much longer to hydrate, and thus to set.

By comparison to lime-based mortars, gypsum mortars have various advantages. First, since they require relatively low temperatures for their processing, they offer an interesting alternative in regions with limited sources of fuel. Second, their setting time can be easily controlled through the addition of modifiers that act as retarders or accelerators, such as organic gum, glue, and starch, or finely ground raw gypsum, and water-soluble salts.

Finally, gypsum mortars dry and harden with negligible shrinkage. They can therefore be used with a minimal amount of aggregates. Slight water solubility and low weather resistance in humid environments are considered their main drawbacks, but these problems have often been bypassed by adding lime or waterproofing agents.

The starting material for making lime is limestone or some other material composed predominantly of carbonate, such as marble, shells, or coral. The main constituent of limestone

is calcium carbonate (CaCO_3 : calcite), but limestone is rarely pure and frequently contains other minerals that can also be subject to physical and chemical changes during the lime-cycle process. When magnesium carbonate (MgCO_3 : magnesite and $\text{MgCa}(\text{CO}_3)_2$: dolomite) represents a significant component, as for example in dolomitic limestone, the resulting product is known as a magnesian or dolomitic lime. The presence of noncarbonate minerals such as clays or other siliceous and aluminous constituents may influence the setting mechanism and, according to their importance, two categories of lime can be distinguished: air lime and hydraulic lime.

In order to be converted into lime, carbonate materials first have to go through two main stages: thermal treatment (calcination) and slaking (hydration). The heating of carbonate minerals at appropriate temperatures causes their decomposition and the removal of carbon dioxide. Calcium carbonate begins to lose carbon dioxide at 700°C , but its full decomposition usually takes place around 900°C . Magnesium carbonate dissociates between 510°C and 750°C . The next stage, known as slaking, consists of mixing the burnt residue with water. Calcium oxide (CaO : quicklime) reacts exothermically with water and turns into calcium hydroxide ($\text{Ca}(\text{OH})_2$: portlandite). Magnesium oxide (MgO : periclase) is less reactive and slowly reverts to magnesium hydroxide ($\text{Mg}(\text{OH})_2$: brucite). Unlike gypsum, lime requires a third stage in order to set, and the nature of this final stage differs according to the purity of the parent material.

Limestone and materials high in carbonate content produce air lime or nonhydraulic lime. Lime made from limestone containing clays and other silicates and aluminates in significant proportions is known as hydraulic lime. Nonhydraulic lime sets by drying and reacting with atmospheric carbon dioxide, to form calcium and magnesium carbonate again. This process, called “carbonation,” is extremely slow, and uncarbonated lime lumps have been observed in mortars several centuries old. Hydraulic property, or hydraulicity, derives from the reaction between calcium oxide and some of the noncarbonate constituents, especially silica and alumina. Intense heat causes these components to react with lime and induces the formation of calcium

silicates and aluminates. When these come into contact with water, they turn into calcium silicate and aluminate hydrates (C-S-H and C-A-H), that is, into low-solubility compounds that confer hydraulicity or the property to set in wet conditions, even under water.

There is strong evidence that, relatively early in the history of lime technology, artificial hydraulic limes were produced by mixing ordinary lime with certain siliceous materials in a finely divided form. In the presence of water, the silica–alumina components present in these materials react in the same way as those naturally contained in some limestones. Such materials, which have been given the name “pozzolan,” may be natural or artificial. Natural pozzolans mainly consist of materials of volcanic origin such as ash, tuff, and other pyroclastic rocks. Other forms include opaline cherts, shales, and some diatomaceous earths.

Historically, artificial pozzolans were obtained through the pulverization of fired clay-based materials such as bricks, tiles, and pottery. Nowadays common alternatives include specifically manufactured clay products (metakaolin) and industrial wastes (fly ash, silica fume, rice husk ash, and so on).

Initially the term “pozzolan” was used to describe the volcanic materials (*pozzolana*) mined in the vicinity of Pozzuoli near Naples (Italy) and employed since Roman times in the manufacture of hydraulic binders. It is generally believed that the practice of adding natural and artificial pozzolans to lime appeared during the first millennium BCE and was diffused through the Greeks and the Etruscans to the Romans. Recent discoveries and archaeological records from other regions rather suggest that this practice had antecedents and parallels not only in the Neolithic Levant and in the Bronze Age eastern Mediterranean region, but also in more distant areas such as pre-Hispanic Mesoamerica (Hauptmann and Yalcin 2000; Theodoridou, Ioannou, and Philokyprou 2013; Gillot 2014).

Like gypsum, lime offers various advantages over mud in terms of versatility, applicability, strength, and durability. Furthermore, compared with gypsum mortars, lime mortars better retain their integrity in damp environments. Hydraulic mortars are also useful for the construction of hydraulic works and immersed structures. From a technological perspective,

however, lime production is more expensive and energy-consuming, since the calcination of carbonate materials requires a substantial amount of fuel to maintain high temperatures for several hours or days. Prior to the advent of modern kilns fueled by oil and gas, lime was produced in various types of kilns, from the earliest open-air bonfires and pit ovens to traditional, built lime kilns. The load was not necessarily well separated from the fuel, and ash and charcoal inclusions regularly contaminated the lime. In addition, as firing temperatures and heat distribution were not easily controlled, lime was not always burned uniformly. Under- or overburned particles inclined to slake slowly or incompletely were frequent.

Quicklime was converted into lime by various dry and wet methods. Dry slaking was often achieved by mixing lime with a limited quantity of water or damp sand. Nonhydraulic lime was also commonly slaked to a putty, then set aside for long periods of time in order to ensure that all particles were fully slaked and to allow the product to mature or “age.” When required for use, lime powder or putty was blended with aggregates and, if necessary, with additional water. Well-graded natural sand and pulverized stone were the most common aggregates. Other aggregates included chunks of chalk, shells, and various recycled materials like fragments of brick, pottery, and old mortar. Considerable variation occurred in the binder–aggregate ratio but, ideally, the aggregate was mixed with just enough binder to fill the voids between its particles. Modern specifications for lime mortars usually prescribe one part of lime for three parts of aggregate. Old lime mortars rather show a ratio that varies between 1:1 and 1:4. Finishing plasters and renders were typically prepared with a higher proportion of lime.

Additives were normally added in small quantities. A wide variety of additives have been used; they include various dairy products and substances of animal or vegetal origin (ash, fibers, dung, blood, oil, glue, resin, sugar, beeswax, beer, milk, rice, etc.). Inorganic and organic colorants were also sometimes added to surface coatings composed of water-based solutions of lime (limewash).

Cement-based mortars

At the dawn of the industrial revolution, the search for optimal hydraulic binders led to significant developments in lime-mortar technology and opened the way to the manufacture of a new class of materials called “cements,” in an allusion to the ancient Roman concrete (*opus caementicium*). Cements are highly hydraulic binders, made by calcining either natural calcareous materials rich in clay minerals (natural cement) or artificial mixtures of calcareous and argillaceous materials (artificial cement). During the hundred years between 1750 and 1850, various attempts were made to produce such binders. Different cementing products appeared on the industrial market, the most famous being those of James Parker and Joseph Aspdin. Natural cements, such as Parker’s Roman cement, patented in 1796, appeared first and predominated until the late nineteenth century. Later, however, they fell into disuse, as artificial Portland cement, first patented by Aspdin in 1824, became the norm.

The technological improvements and advances associated with the manufacture of Aspdin’s product provided the basis for the modern cement industry. Materials with high proportions of clay minerals were selected and calcining temperatures were increased, so that they approached the sintering point (around 1,450°C). At this temperature, carbonate and clay minerals fuse to form complex compounds such as dicalcium and tricalcium silicates (belite and alite). On cooling, the molten mass vitrifies and is converted into hard clinkers, which must be repulverized to generate a powder highly reactive with water. When water and cement are mixed together in the course of preparing a paste or a mortar, the hydration and setting processes start almost instantaneously.

Like hydraulic lime mortars, cement-based mortars retain their integrity and stability under either atmospheric or submerged conditions.

With their quick setting time, impervious character, and high compressive strength, cements were rapidly adopted, first for large industrial application and then in all forms of construction. During the last two centuries the demand for cementing products has increased, and constant efforts have been made to meet the requirements of modern building and engineering industries. This has resulted in the emergence not only of a variety of specialized cements, but also of a large number of new additives and chemical admixtures.

Characterization of Ceramics

P. DEGRYSE

Centre for Archaeological Sciences, Belgium

A. J. SHORTLAND

Cranfield University, UK

Ceramics and archaeology

While this definition may vary between research disciplines and the timeframe under consideration, ceramics can be described as objects made out of clay that has in some way been processed. Clay is a naturally occurring geological deposit, usually formed from the weathering of rocks. It is made up of clay minerals mixed with a greater or lesser amount of other minerals. Common clay minerals encountered in the deposits used for archaeological ceramics include kaolinites, smectites, chlorites, and illites. Naturally occurring clay bodies often combine a wide range of different clays within these groups. Different clay types give slightly different properties to the ceramics that are made from them. “Clay” is used in this text as a term indicating a natural geological deposit made up mainly of clay minerals, often mixed with other minerals.

The simplest type of ceramic would be clay that has been shaped and dried, while more complicated ceramics would be fired in a kiln at temperatures that fuse the outer layer of the clay minerals in its body and give the object strength and resistance to moisture and heat. In arid climates, dried or baked clay bricks are still used in architecture as they have been for many thousands of years. However, such baked clay is vulnerable to damp, and rapidly turns back to clay when subjected to contact with water. From the Neolithic, clay was shaped and *fired* as vessels to enable it to keep its shape and be used in cooking and storage. The most commonly found ceramic therefore consists mostly of fired clay (or “earthenware”), possibly combined with other materials.

Ceramics are regularly made up of clay with other additions that have been deliberately, or accidentally, added to it. The most common deliberate addition to the clay is temper, which changes the properties of the clay during both firing and use. Temper can include sand, straw, rock fragments, ground-up broken ceramics (known as grog), and many other materials. The reason for the selection of a particular temper can be technological, for example, to reduce shrinking in drying and firing, but it can also be ritual.

Ceramic vessels can be shaped by hand-modeling, coiling, slabbing, molding, and throwing on various sorts of wheels (Orton, Tyers, and Vince 1993). Each of these techniques can leave traces in the appearance of the ceramic. This appearance can be changed once again by the firing process, which can change the color of the clay or even partially melt the ceramic body if fired at high enough temperatures.

The surface of the ceramics can be treated with different techniques to alter the properties of the ceramic (Orton et al. 1993). Commonly seen are relief, slips, and glazes (see GLAZES, SLIPS, AND PAINTS). It is very common for the surface of vessels to be decorated with incised patterns before firing. Also, prior to being fully dry, the surface of a ceramic can be polished before firing (known as burnishing), which results in a smoother surface. Another surface technique is to apply a very pure clay, painted onto the surface, or dipping the ceramic into it, known as a slip. A wash is a very thin slip layer that does not entirely coat a ceramic. Slips can be contrasting colors and can create polychrome vessels. A final possibility is to apply a glaze, which is commonly put onto the ceramic as a slurry and then fired to create a glass surface layer. Glazes are essentially a glass adhering to the surface of the ceramic, can have many colors and can themselves be painted (see GLAZES, SLIPS, AND PAINTS).

The abundance and ubiquity of ceramics on archaeological sites is the result of the wide availability of the raw materials for their production, the relative technological ease of making ceramics, their fragile nature and the limited options for

DOI: 10.1002/9781119188230.saseas0085

reuse or recycling (Shortland and Degryse 2017). The fate of most broken ceramics is to be discarded. Most ceramics, however, especially fired ceramics, are very resistant to degradation when buried. Once discarded, they tend to pass relatively unchanged into the hands of the archaeologist, where a reconstruction of the shape of vessels or an identification of the raw materials used is possible. Research questions to be answered range from how and when ceramics were made, what they were used for, to where they were produced.

Typo-chronologies of ceramic vessels are studied on virtually every excavation worldwide, as the prime stratigraphic dating tool in archaeology (see *DATING IN ARCHAEOLOGY AND SERIATION*). Ceramics are also a proxy for the study of many archaeological questions, from craft organization and trade patterns, to social stratigraphy (presence of exotic goods), subsistence strategies (provenance of food based on the provenance of their containers, residue analysis on ceramic cooking pots and containers), and chronological changes in the standard of living (changing proportions of import versus local production). The identification and description of rare imported, foreign vessels or sherds in a mass of locally produced wares is perhaps traditionally the most important question asked in the study of ceramics. Non-local ceramics, because of the opportunity they give for the plotting of ancient trade and exchange networks, as well as the possibility of identifying high-status individuals or sites, are perhaps some of the most interesting parts of the analysis of this material. Moreover, the technology of producing ceramics, while in essence simple, varies through time and is adjusted by different societies. Material culture studies, in particular *chaîne opératoire* reconstructions, focus on different technological methods used to produce materials, alongside specifically studying human agency in making materials (see *MATERIAL AGENCY*). In essence, ceramic studies can range from studying which material was used to make a pot, to investigating which choices were made to make the ceramic significant in the framework of a particular time and culture (Arnold 2008). This has led to the discussion of the place of ceramic houses and their workers within society, and how the decisions they are

making both shapes and is shaped by the culture in which they are operating (Orton et al. 1993; Arnold 2008). Ceramics may serve as transmitters of information about their producer, owner and user, as they are part of a “material culture language” (Hodder 1986; Arnold 2008) (see *MATERIAL CULTURE*). Ceramics, therefore, are extremely useful both to the societies who have employed them, as well as to the scientists who study them.

Ceramics and archaeological sciences

As discussed above, ceramics analysis has been used to answer a range of questions, of which “how was it made”, “what was it used for” and “where was it made” are the most obvious ones (see *ARCHAEOLOGICAL SCIENCES*). It could be argued that for all archaeological artifactual evidence, the study of the provenance of raw materials, the production technology and trade of raw materials, and the study of formed artifacts must be based heavily on scientific analysis. As with the study of many material types, ceramics can be studied using a range of different equipment ranging from the naked eye or a hand lens to very expensive laboratory equipment, each of which gives different information of contrasting accuracy and reliability.

Pollard and Heron (2008) described the development of archaeological chemistry in detail (see *CHEMISTRY IN ARCHAEOLOGY*). In 1895, T. W. Richards published the first wet chemical analysis of archaeological ceramics in the form of Athenian pottery. However, in comparison with the well-established tradition of typo-chronological studies of archaeological materials, the more routine use of exact scientific tools has a fairly young tradition of research, mainly developed after World War II, closely related to the development of analytical techniques. Felts in 1942 microscopically studied ceramics excavated at Troy, but the most important archaeometric techniques for ceramological research were presented in 1956 by Anna Shepard and in 1970 by David Peacock. Since then, exact scientific techniques for ceramic studies have been used more and more frequently (and not only on ceramics, but on many different material categories).

A key concept in ceramic studies is that of *fabric* (Peacock 1977). The fabric analysis of a ceramic is the study and classification of this material based on the characteristics of the clay paste and their inclusions. This includes the color of the matrix, hardness, feel, nature of the fracture, firing process, production process, and the nature, amount, size and sorting of the inclusions. The resulting macroscopic groups are often referred to as wares: recurring combinations of distinctive attributes including color, temper, vessel form and type of decoration and techniques used (Henrickson 1994). After ceramics are sorted into groups by these relatively simple techniques, then the next stage is to try to characterize the groups. There are two main approaches to this: mineralogical and chemical. Often, the results of (macroscopic) fabric analysis are in perfect accordance with scientific studies. Nevertheless, in many cases a discrepancy between fabrics, wares and “petrographic wares” or geochemical groups is observed. While it is relatively easy to say that one group of ceramics is compositionally identical or different to another in terms of composition, it can be difficult to say *why* that might be so. This could be connected to the use of different clays, different temper or amount of temper, to clay processing or firing, and even the post-depositional environment and alteration.

Mineralogical approaches

The most common method of characterizing a group of ceramics is to examine its mineralogy. Thin-section petrography, a geological technique derived from the study and description of rocks, is still the main technique used for this (see PETROGRAPHY AND CERAMICS). Fragments of sherds are glued to a glass slide and polished down to a thickness of 30 μm , at which point most minerals in stone or ceramics become translucent. Under a polarizing light microscope, the minerals in the sample interact with the light going through them, generating colors and other properties characteristic of the minerals involved. As long as the ceramic is coarse-grained enough for the minerals to be visible, this is a very well established method for identifying raw material

mixtures used, formation processes, firing temperature, and oxidation state. It requires a good level of expertise and experience to be able to describe ceramic thin-sections, which, even to those geologically trained, can be difficult. Many textbooks and review papers exist on the basics of thin-section petrography in general, or ceramic petrology in particular (Reedy 2008; Quinn 2013; Braekmans and Degryse 2016).

Other possibilities for assessing the mineralogy of ceramics is to use scanning electron microscopy (SEM) or X-ray diffraction (XRD) (see XRD AND MATERIALS ANALYSIS). In SEM, minerals are identified by a combination of morphology and contrast or by using an attached energy dispersive spectrometer to analyze the composition of individual phases. It is possible to automate the identification of grains on the SEM, so that the whole section is mapped for different elements, and then grains that are the same are grouped together and counted. This can give good quantitative results for the mineral analysis of the ceramic or clay. Also in X-ray diffraction, next to identifying the nature of the mineral phases present in a sample, a quantification of the amount of these minerals present can be given.

None of the mineralogical techniques are suitable when the ceramic becomes too fine-grained (for petrography, that is when individual minerals can no longer be discerned), or too highly fired (for petrography, SEM and XRD: a large portion of the ceramic will melt into a glass, and the bulk mineralogy may change significantly), to have a recognizable mineralogy. In these cases, and to make a direct comparison to clay resources, chemical approaches have to be used.

Chemical approaches

A second major approach to the analysis of ceramics is to go from the optical, hand-specimen grouping to bulk chemical analysis. Where the early techniques of chemical analysis of ceramics used wet chemistry, this has now been superseded by an array of other techniques, especially atomic absorption spectrometry (AAS), neutron activation analysis (NAA) (see NEUTRON ACTIVATION ANALYSIS (NAA)), X-ray fluorescence (XRF) (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), optical emission spectroscopy (OES), and

inductively-coupled plasma (ICP) (see ICP-MS AND MATERIAL ANALYSIS) techniques (see INAA AND MATERIAL ANALYSIS and ICP-MS AND MATERIAL ANALYSIS) (e.g., Pollard and Heron 2008). To use these techniques, a sample is ground up and either dissolved in acid or pressed into a powder pellet and irradiated. The type of technique chosen for ceramic or clay analysis depends on which chemical elements are to be identified, and the likely concentrations. Bulk chemical analysis is possible for almost all elements, with detection limits for some techniques as low as parts per billion (ppb) or even parts per trillion (ppt). Chemical analysis, combined with statistical approaches (see STATISTICS IN ARCHAEOLOGY), can be very good at grouping ceramics and determining outliers (see STATISTICS IN ARCHAEOLOGY; POTTERY DATA QUANTIFICATION; and PRINCIPAL COMPONENT ANALYSIS). However, it does hide the detail of individual ceramic technologies in a way that mineralogical approaches do not.

Also, (semi) non-destructive techniques, which require no sampling and do (nearly) no damage to the object under investigation, are used regularly in ceramic studies (see NONDESTRUCTIVE COMPOSITIONAL ANALYSIS OF CERAMICS). While NAA is usually applied to powders to avoid possible heterogeneity in ceramics, it is in principle possible to irradiate a whole object and obtain very accurate trace element data. Also techniques such as portable XRF (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)) and laser ablation ICP have no or very little impact on a ceramic's integrity, and give a full array of major to trace element data (see INAA AND MATERIAL ANALYSIS and ICP-MS AND MATERIAL ANALYSIS). They are, however, surface techniques, and as such very sensitive to sample inhomogeneity. Moreover, calibration of pXRF to obtain (semi-) quantitative data is not always evident.

In pottery studies, it is assumed that the chemistry of sediments and ceramics made from them approximately reflects the main characteristics and the chemical properties of the rocks from which they were derived in the catchment area or geological system that provided them. This makes possible the direct comparison between the chemical characteristics of several likely clay resources and ceramic ware groups. Ethnographical studies of potters have shown that the raw

materials of ceramic production tend to be gathered very close to the kiln site, usually within a day's journey there and back (Arnold 2008). This means that the raw materials of local ceramics are derived very locally to the production site, and limits the number of clay resources that need to be investigated. Discarded, misfired sherds, known as wasters, are very useful for provenance studies, as these are often thrown away in situ, or in close proximity to the production site, after a failed firing process. They give an excellent idea of what wares the site was producing.

Just about every element of the Periodic Table has been used at some time to compare the typical composition of resource materials to that of archaeological artifacts. Depending on the nature of the materials analyzed (e.g., clay compared with ceramic), elements are chosen for their occurrence as major or trace elements and the nature of the geological-mineralogical information they provide. For example, aluminum, magnesium and potassium are typical major elements, which provide information on the type of clay minerals used. However, since most clays have similar, if not overlapping, major element compositions, there is little resolution in such analysis to distinguish different ceramic origins. The variation in trace elements, such as the transition metals or the rare earth elements (REEs), may then be much more useful in distinguishing between the different raw materials used. Overall, trace element analysis has been successful in answering archaeological questions on ceramic raw material provenance, recipes and manufacturing processes, and technological evolution.

Other approaches

In addition to the study of the ceramic itself to determine use, there is also the possibility of looking at residues within the pores of the ceramic, which may reflect what was held in a container or how a ceramic vessel was used (see FOOD RESIDUE ANALYSIS). This organic residue (see ORGANIC RESIDUE ANALYSIS) work can involve painstaking preparation and analysis of hundreds of potsherds over a wide geographical range. A wide range of biochemical components (biomarkers) including lipids and proteins derived from animal fats,

waxes, dairy products, and human remains can be preserved in and identified from pottery, and answer questions on diet, climate and subsistence (Degryse and Bentley 2017) (see DIET AND CARBON ISOTOPES; DIET AND NITROGEN ISOTOPES; DIET AND SULFUR ISOTOPES; and DIET AND TRACE ELEMENTS).

In the past decade(s), more unusual (rare and expensive) methods and equipment such as synchrotron radiation facilities have been used to look at archaeological ceramics. Recent developments also applied radiogenic isotope (see ISOTOPES) ratios to the analysis of pottery ($^{87}\text{Sr}/^{86}\text{Sr}$, $^{143}\text{Nd}/^{144}\text{Nd}$, $^{207}\text{Pb}/^{206}\text{Pb}$, etc.). It needs to be stated, however, that these studies are best carried out only when no other technique provides sufficient data for answering research questions (see SYNCHROTRON-BASED X-RAY ANALYTICAL TECHNIQUES AND MATERIALS ANALYSIS; X-RAY ABSORPTION SPECTROSCOPY (XAS, EXAFS, XANES); and NON-STABLE ISOTOPES IN ARCHAEOLOGY).

Ceramic characterization

There tends to be a hierarchy of techniques used in the analysis of ceramics, starting simply and cheaply with the bulk of the samples, and selecting smaller numbers at each stage to be subjected to analysis by more lengthy and expensive techniques (Shortland and Degryse 2017). Although providing a substantial amount of information on their own, the simultaneous use of several methods provides a more robust framework for interpreting ancient potteries. When time and money permits, a combination of petrographical and chemical approaches gives the best combination of information and is most likely to answer archaeological questions on provenance, trade and exchange, or use (Degryse and Braekmans 2014). The very ubiquity of ceramic finds on the majority of archaeological sites requires an investment in their study. A carefully constructed sampling strategy informed by clear questions and combined analytical techniques is essential to use ceramic characterization effectively as a method to unveil different aspects of our past.

Characterization of Metals and Alloys

BLANCA MALDONADO

El Colegio de Michoacán, A.C., Mexico

Metals are a group of inorganic, crystalline materials that can either occur naturally or result from the pyrotechnological processing of minerals. When found in metallic state in nature (i.e., not produced from ores by smelting), they are called native metals. Like all crystallized substances, metals are characterized and defined by their chemical composition and crystalline structure. Metals often contain only one chemical element with trace impurities (e.g., gold, copper, lead, aluminum). Their chemical content can be divided into “major” elements and “trace” elements. Major elements are those that define the material in question; they are usually measured as percentages and are commonly above 1 percent of the chemical composition of the material. Trace elements, on the other hand, are elements that occur in such small concentrations that they do not change the essence of the material; they usually have concentrations below 0.1 percent. In archaeology, trace elements are used primarily for provenance studies.

Ores are minerals (i.e., naturally occurring, inorganic, crystalline materials) that, when smelted, yield metals that have economic or social value for human societies. Smelting is a process by which an ore (one or more minerals that contain the metal) is heated, so that the metal in it is reduced to its metallic state and thus separated from the other chemical elements (Rapp 2000, 364–65). Some metals are alloys, that is, combinations of metals; for example, bronze is an alloy of copper and tin. This means that two or more different metals were melted or brought to liquid state, then mixed together. When the alloy cools, it has some of the properties of all the metals that were combined to form it. The discovery that a metal like copper, when combined with other substances, can acquire superior properties

apparently occurred in Southwest Asia around 3,500 BCE.

Metals, both pure and alloyed, have played a significant role in society throughout the ages. In ancient metallurgy, the transition from a copper technology to one based on bronze involved mixing copper with a range of arsenic-based compounds. The question here is whether these alloys were produced intentionally or were the accidental result of the composition of naturally occurring ores. Answering this question required characterizing (1) the metal objects unearthed by archaeologists, (2) slag (residues from smelting), and (3) the ores themselves. Hence our knowledge of the origins of copper-alloy metallurgy is largely indirect, as it derives from analyses and interpretations of the composition and structure of those materials (Rapp 2000).

The characterization of metals consists of the broad process of testing and measuring their structure and properties and the methods used to gather this information. This often involves techniques derived from archaeology, materials science, and geology for conducting chemical analyses, determining the sources of raw materials, and identifying ore-processing and metalworking techniques (Rapp 2000, 364). Scholars generally acknowledge the value of scientific and analytical techniques for increasing the information potential of archaeological findings by providing the framework for archaeometallurgy—the study of ancient and historical metallurgical technology that encompasses all aspects of metal production, from artifact manufacture to use and disposal (Pollard and Heron 1996).

Metals such as gold, silver, copper, tin, lead, and iron were among the earliest materials processed by ancient peoples. The vast majority of ancient metal artifacts, except for gold and platinum, were obtained by smelting metalliferous ores to produce different metals and alloys. Because of their continued use in and importance for modern society, great effort has been invested in learning about their synthesis, properties, and processing. Two major advances in the study of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0078

metals and alloys were brought about by the twin discovery that their microstructure was critical to their observed properties and that this structure could be modified by the processing history of the metal (Holloway and Vaidyanathan 2010).

Both the macroscopic external and the microscopic internal surfaces of metals and alloys are critical to their properties and performance in specific contexts. For example, ancient peoples often used metals like gold and silver, which were shiny and attractive, a practice still reflected today in the wearing of rings, bracelets, and earrings. The esthetic appeal of those metals results from their interaction with light, which depends crucially on their surface composition and topography. Analytical techniques have been developed that allow analyses of the top atom layer—or top 10 layers—of artifacts to determine why the reflection of light changed (Holloway and Vaidyanathan 2010, 1). The study of the metallographic structure of metal artifacts through different analytical techniques is well established and essential for understanding manufacturing processes.

Chemical properties of metals and alloys

Metals are highly reactive in most gaseous and liquid environments. Hence, for most of them, pure metallic forms rarely exist in nature; metals appear rather as oxides or minerals. This is why it is technologically and scientifically important to understand the chemical interactions of metals and alloys with the varied environments in which they were used. Given the importance of the surface and interface properties of metals, and also because crucial information is often hard to obtain, several tools have been developed to gather data. Each technique has significant advantages but also important limitations, and most can be used in straightforward or more sophisticated ways (Baer 2010).

The chemical properties of a metal surface are determined by analyzing such characteristics as composition, thickness, reaction (or growth) mechanism, and chemical and physical structure. Different analytical methods for examining surface and interface features can be used in a variety of ways to obtain distinct types of data. Valuable

results are often obtained when the analyst fully understands both the problem of interest and the technique used. The exact nature of the composition and structure of metals is critical for the method applied. In some cases, conducting the study requires intentionally modifying the surface composition. Modifying the surface is a key step in identifying specific properties related to the scientific study involved and the technology applied. The aim is to alter some property of the surface or region close to the surface of a material, but without degrading its “bulk” properties (Baer 2010, 43).

Different surface-sensitive methods of analysis provide information on the chemical properties of metals. There has always been a need for the creative application of diverse methods, which should maximize our insights into the chemical properties of metal surfaces. Fortunately, technological advances in current methods and the development of novel techniques are opening new opportunities for analysis. For example, surface analysis measurements are being increasingly combined with measurements obtained through chemical reaction techniques (Baer 2010). The scale of the structures observed during characterization ranges from angstroms, as in the imaging of individual atoms and chemical bonds, to centimeters, as when imaging coarse grain structures in metals (Leng 2008).

Characterization methods

The last two decades have witnessed major advances in the types of equipment available, the application of methods, old and new, enhanced to meet analytical needs. Areas of analysis that have seen significant development include decreases in beam size (i.e., finer area or volume of analysis), quantification (understanding of instrument characteristics and quantification methods), the elaboration of *in situ* methods (XRF, FTIR), improved databases, and the establishment of recognized procedures and standards. It is likely that the near future will see greater use of *in situ* real-time measurements in combination with well-established *ex situ* techniques (Baer 2010).

The process of characterizing metals and alloys for archaeological research depends on

the problem to be answered or resolved. Studies may focus on such issues as manufacturing technology, the origin of metal ores, smelting technology, casting techniques, gilding, corrosion, or authentication. Each one of these elements requires a distinct analytical approach (Rapp 2000, 365). Certain characterization techniques, such as basic optical microscopy, have been practiced for centuries, but new test instruments, methods, and methodologies are constantly being developed—and afterwards updated and improved. The introduction of the electron microscope and secondary ion mass spectrometry in the twentieth century, for instance, has revolutionized the field, for this technique allows the imaging and analysis of structures and compositions at much smaller scales than those reached by earlier methods. This has stimulated a great improvement of our understanding of the properties and behaviors of different materials.

Regarding the choice of analytical tools, there is no universal method for analyzing metals. No single technique holds all the answers; no method is necessarily the best in all situations, for all objects or problems. Nor can analyses be conducted using one sole approach, no matter how careful or creative it may be. Each case is specific and requires a different set of responses. The diverse forms of ores and mineral deposits entail that one particular element or suite of elements may constitute the critical distinguishing factor in some studies, though it may be irrelevant in others (Pollard and Bray 2014).

Nondestructive characterization techniques

Nondestructive testing methods have increased in importance in the study of archaeological objects. Among such methods, X-ray fluorescence (XRF) is perhaps the most popular one; and it is now available in the form of a portable handheld system. XRF offers considerable advantages because it can identify and quantify different metals simultaneously (Jenkins 1988). It is particularly well suited for identifying and quantifying metals and alloys, since most of the alloys used in antiquity (gold–silver, bronzes, and brasses) are made up primarily of heavy metals, which show up well under XRF. Of the metals known in ancient times,

however, iron is problematic, because the main alloying elements (carbon, phosphorus) are too light to be detected by XRF. The disadvantages of XRF thus include its lack of sensitivity when it comes to the smallest amount of a specific element that can be measured accurately.

In this context, proton-induced X-ray emission (PIXE) spectrometry emerged as a useful nondestructive analytical tool, which can simultaneously determine heavy and light oxides, as well as minor components. Recent instrumental developments in PIXE have resulted in highly focused proton beams (down to a few microns), which allow chemical analysis and elemental mapping on a microscopic scale. This technique is called microPIXE, or μ -PIXE. Variants of PIXE include particle- (or proton-)induced gamma-ray emission (PIGE), which can be used to detect some of the lighter elements that XRF or other methods do not detect (Pollard and Bray 2014). Ancient metals, especially alloys, however, are of a heterogeneous composition and contain a variety of phases, so PIXE analyses may not always produce representative results (Hauptmann 2007).

Semi-destructive characterization techniques

From an analytical perspective, better results are attained by removing a small sample from the metal object whenever that is possible, polishing it, and mounting it for analysis. This procedure allows further physical examination of the artifact (e.g., metallography, hardness) prior to any chemical analysis. Modern metal-characterization techniques can ascertain the levels of achievement of ancient metalsmiths (Pollard and Bray 2014). The microstructure of most metals used in antiquity preserves evidence of their thermal and mechanical history that can be observed easily with the metallographic microscope.

Evidence of work hardening (or strain hardening) and annealing is preserved in these microstructures. Metallurgists make wide use of the metallographic microscope in analyzing the structural features of metals and in identifying distinct compositional phases. Once a sample is taken, numerous options of analytical instrumentation are available for the characterization process. The two most common ones used

today are based on electron microscopy (EM) or inductively coupled plasma spectrometry (ICP). The metallographic microscope used in conjunction with the electron microscope can provide the structural and chemical analysis needed to address most archaeometallurgic problems (Rapp 2000).

Microscopy As a category of characterization techniques, microscopy probes and maps the surface and subsurface structure of materials—in this case, metals. These techniques can use photons, electrons, ions, or physical cantilever probes in order to gather data on the structure of a sample over a range of length scales. Common examples of microscopy instruments are optical microscopes and EM. For the last few decades, EM has been the most widely used technique for characterizing metals. While the microscopy side of the instrument employs a beam of electrons, the actual chemical analysis relies primarily on the detection of X-rays.

EM has many advantages. It can produce high-resolution images of the physical structures present, as well as micropoint chemical analyses and two-dimensional (2D) chemical maps of the exposed surface. This technique has been known by several names—for example electron microprobe analysis (EMPA), scanning electron microscopy (SEM), scanning electron microprobe with energy-dispersive spectrometry (SEM-EDS), SEM with wavelength-dispersive spectrometry (SEM-WDS)—depending on the particular configuration available. The disadvantage of nondestructive XRF is that it is a surface-only analysis with low sensitivity (Pollard and Bray 2014).

Spectroscopy Spectroscopy is a broad field with many subdisciplines, each with numerous implementations of specific spectroscopic techniques. These techniques are applied to investigate the chemical composition, composition variation, crystal structure, and photoelectric properties of metals and other materials. Some common instruments are energy-dispersive X-ray spectroscopy (EDX), wavelength-dispersive X-ray spectroscopy (WDX), X-ray diffraction (XRD), mass spectrometry, Fourier transform infrared spectroscopy (FTIR), and thermoluminescence

(TL). ICP is an especially sensitive quantitative analytical tool that measures the wavelength and intensity of the light emitted by a sample. It is used to detect trace elements as its primary goal but can usually detect many elements, down to the level of “parts per billion” (ppb, equal to 1 atom in 10⁹), from a very small specimen.

ICP requires that the elements to be analyzed be in solution, but more recently a device has been implemented that uses a pulsed laser to vaporize (ablate) a small volume from a solid sample into a gas stream, which then enters the plasma torch. This is known as laser ablation ICP (LA-ICP-OES). One disadvantage of ICP methods is that, while in theory all elements except argon can be determined, certain unstable elements require special facilities for the handling of the radioactive fumes from the plasma. Also, ICP has difficulty handling halogens, so a special optics is necessary for the transmission of very short wavelengths. The elemental analytical capabilities of most ICP techniques are comparable to, though somewhat better than, the data previously produced by neutron activation analysis (NAA), which had long been the preferred means of analyzing trace and ultratrace elements in archaeological and geological science (Pollard and Bray 2014).

Isotopic characterization of metallic archaeological artifacts

In addition to the chemical composition of a metal artifact, another major attribute that can be measured is the isotopic composition of its elements. Isotopes are atoms of a chemical element with the same atomic number and position in the periodic table and with nearly identical chemical behavior, but with different atomic masses and physical properties. Chemically speaking, the isotopes of an element behave identically, but sometimes take part in chemical reactions or physical transformations (e.g., evaporation) at slightly different rates. This is because the difference in mass of the isotopes means that the bond energy between one isotope and oxygen, for example, will be slightly different from that of another isotope with oxygen. Thus, over the course of various chemical reactions or transport phenomena, the ratio of one isotope to another of the same element may change. In the case of

chemical reactions, this is called fractionation. This means that the environmental or geological history of certain metals can be reconstructed by measuring isotopic ratios.

Almost all metals of interest to archaeometallurgy have more than one naturally occurring isotope. In fact, elements with only one isotope are exceptional in nature. The most relevant ones here are gold, which occurs naturally only as ^{197}Au , and arsenic (^{75}As). Many, such as copper (Cu, with the two isotopes listed above) and silver (^{107}Ag and ^{109}Ag) have a pair, but a significant number have several stable isotopes, for example iron (Fe, four), lead (Pb, four), nickel (Ni, five), zinc (Zn, five), and, topping them all, tin (Sn, ten). There is thus plenty of scope for measuring isotopic ratios among the metals of interest to archaeologists. By far the most intensively studied isotope is lead, with four stable isotopes, ^{204}Pb , ^{206}Pb , ^{207}Pb , and ^{208}Pb . The last three are the stable end members of the three long natural radioactive decay chains found in nature, starting with uranium (^{235}U and ^{238}U) and thorium (^{232}Th) (Pollard and Bray 2014).

Lead isotope analysis (LIA) is used in geoscience to understand the geological history of ore formation, but was rapidly adopted in archaeology, initially to assign lead and silver artifacts to a particular mining region or deposit. LIA was eventually accepted as a new and “secure” method for provenance studies of metal artifacts (Hauptmann 2007). LIA offers a sensitive analysis of masses in which isotope ratios are measured with a mass spectrometer. The decisive point that makes the LIA so valuable for provenance analyses is that lead isotope ratios do not change during metallurgical processes. The isotope pattern remains constant regardless of what temperature the ore is roasted at, under what reducing-oxidizing conditions the metal is smelted, or how often it is resmelted. Hence the pattern is characteristic of a particular deposit and allows a secure assignment of the finished product to the initial raw material (Pernicka 1987). Problems such as the mixing and reuse of metals from different sources, as well as limited reliable data and the contamination of samples, can, however, present difficult problems in interpreting LIA results (Budd et al. 1996). Bearing in mind the particularities of each case study, it is essential to link the chemical and isotopic

Figure 1 The Nebra Sky Disk, by Dbachmann, CC BY-SA 3.0. <https://commons.wikimedia.org/w/index.php?curid=1500795>.

characterization of metals around a systematic question and methodology.

Characterization of metals and alloys: A case study

One of the most significant cases in the field of the characterization of metals and alloys is the study of the Nebra Sky Disk. Found by two treasure hunters in 1999, this artifact displays the world's oldest known concrete depiction of astronomical phenomena (see Figure 1). Dating to 1600 BCE (Middle Bronze Age), this bronze disk is embossed with gold leaf symbols that appear to represent a crescent moon, the sun (or perhaps a full moon), stars, a curved gold band interpreted as a sun boat, and an additional gold band on the edge of the disk that probably represents one of the horizons. Another gold band originally located on the opposite side is missing. Given its somewhat obscure provenance, the disk has gone through a series of rigorous laboratory tests designed to prove its authenticity (Pásztor and Roslund 2007).

In addition to the question of the legitimacy and origin of this object and its raw materials, the analyses performed on the Nebra Sky Disk include in their focus the techniques of manufacture and the history of production that lie

behind it. Since its first impoundment in 2002, the disk has been thoroughly investigated by a number of research groups from different institutions. These analyses have included, among other methods, the chemical and physical characterization of the materials using X-ray fluorescence (XRF), synchrotron XRF, X-ray diffraction (XRD), computer tomography, isotope ratio mass spectrometry (IRMS), metallography, and both optical and scanning electron microscopy.

Important evidence for the authenticity and antiquity of the Nebra Sky Disk was provided by the Halle Institute for Archaeological Research in Germany. According to its findings, the copper used on the disk can be traced to a Bronze Age mine in the Austrian Alps. Tests have also indicated that a unique mixture of hard crystal malachite covers the artifact. Finally, microphotography of the corrosion on the disk has produced images that prove that it was a genuinely ancient artifact (see, e.g., Pernicka and Wunderlich 2002).

Concluding remarks

Archaeometallurgy deals with all the aspects of metal production, distribution, and usage in ancient and historical times. Resolving important research questions on metals and alloys often requires analysis at different scales. Scientific analyses of such materials are widely employed to measure the physical properties and to characterize the chemical composition of objects. A number of characterization techniques are used to examine external metal surfaces through the layers of corrosion that may cover the original metal. The exact characterization required for research on metals and alloys depends on the problems or questions to be answered or solved. Investigations tend to focus on issues such as smelting technology, manufacturing technology, casting techniques, gilding, corrosion, the provenance of metal ores, or authentication, each one of which will involve a distinct analytic approach.

Characterization of Petroglyphs

ROBERT G. BEDNARIK

International Federation of Rock Art Organizations,
Australia

The world's rock art can be conveniently divided into two principal components of roughly equal quantities—pictograms and petroglyphs. The former were created by an additive process, that is, material was added to a rock surface, while in the production of petroglyphs, material was removed from the rock. Consequently pictograms include rock paintings, stencils, prints, pigment drawings, and beeswax figures. Petroglyphs, made by a reductive process, include engravings, percussion petroglyphs, abraded petroglyphs, and finger flutings in caves (see various techniques in Figure 1). This division is useful because it corresponds not only to the two basic technological classes of rock art, but also to various methods of its study, for instance in age estimation or conservation science.

Another factor separating pictograms and petroglyphs is that the former rarely survive out of caves (see CAVES AND FISSURES) from the Pleistocene, whereas petroglyphs are more resistant to natural deterioration processes, particularly on weathering-resistant rock types such as granites and quartzite. Most of the world's surviving Pleistocene rock art consists of petroglyphs, especially where they are deeply pounded and relatively sheltered. In rare cases these may date from Middle Pleistocene traditions (in central India and the Kalahari Desert) but it is only with the last third of the Late Pleistocene that surviving petroglyphs become more frequent. The longevity of petroglyphs is proportional to the time it takes to create them. Replication has shown that the "composite hardness index" (the measure of a rock's resistance to compressive force) of a rock determines very decisively the production time of percussion petroglyphs. For instance, an identical petroglyph takes about 400 times as long to create

on unweathered quartzite as it takes on weathered sandstone (Bednarik 2016a). These differences are very pronounced, as are the potential survival rates of petroglyphs on different lithologies.

The two principal methods of removing rock mass in petroglyph production are by percussion or by an abrasive action. Impact can be direct, by a hammer-stone, or indirect, by a chisel-like tool combined with a hammer, but there is no ethnographic or replication evidence supporting the view that the second of these methods was applied. Abrasive-action petroglyphs were created by incision or by polishing a surface area. Most petroglyphs have been made with stone or metal tools, although on very soft rocks, bone tools have been used. Another technological separation is between petroglyphs rendered prominent through color contrast, by breaking through a thin surface veneer (patina or weathering zone), and those relying on relief for visibility (where the rock's surface and interior are of similar color). Technologically, the former group is defined as sgraffiti: made by the removal of a veneer to reveal the differently colored rock beneath.

The scientific study of petroglyphs delves primarily into their forensic analysis, that is, the recruitment of empirical evidence for determining the circumstances of their production and use. This includes information about the tools used in their creation, the recovery and study of such implements from sites of occurrence, the direction of tool application, the biomechanics and biokinetics of petroglyph production, identification of multiple applications of individual tools in abrasion petroglyphs, and the replicative studies required to translate such data into testable hypotheses. Another area of scientific concern is the taphonomy (see TAPHONOMY) of petroglyphs, which is intricately interwoven with their lithology, technology, and environmental variables (Bednarik 1994). Various phenomena connected with the characterization of petroglyphs derive from a range of disciplines, such as geology (e.g., the presence of kinetic energy metamorphosis products) or acoustics (e.g., concerning rock gongs, or the acoustic properties of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

sites), as well as many other fields. In view of the frequent inability of archaeologists to effectively discriminate between petroglyphs and natural rock markings of many types, another important consideration concerns the factors distinguishing exogrammatic from other rock markings that may resemble them, and their effective determination. Numerous types of natural markings occurring on rock surfaces can resemble petroglyphs, among them xenoliths, other petrographic marks, weathering and solution marks, tribological marks (e.g. by clastic movement), and rock marks produced by plants and animals. They and even utilitarian anthropogenic rock markings (e.g. drag marks, tool marks) have all been frequently misidentified as petroglyphs.

Dating of petroglyphs

One of the principal concerns in characterizing petroglyphs is the determination of their age. The strategies employed differ significantly from those applied to pictograms, because in contrast to them, there is no analyzable substance available that marks an image's antiquity. The rock mass removed in creating a petroglyph is not credibly recoverable, despite such efforts having been made. Therefore the range of methods engaged in estimating the antiquity of petroglyphs is unique. As in all dating work, the target date

(time of execution; Dunnell and Readhead 1988) is the preferred variable sought, but in the case of petroglyphs, only two methods have so far been applied to securing such results: microerosion analysis and patina colorimetry. Archaeological excavation, for instance, can only provide minimum ages, as does the quantification of fluvial erosion wear and surface retreat; or lichenometry, optically stimulated luminescence (OSL) analysis (see OPTICALLY STIMULATED LUMINESCENCE) or radiocarbon sampling of insect nests. Similarly, the determination of uranium-series products of carbonates or ferromanganese substances, the ^{14}C analysis of carbonates and oxalates, or cosmogenic radiation products (see COSMOGENIC DATING) only provides either minimum or maximum ages under favorable conditions. Cation ratio determination of accretionary mineral deposits has been rejected, and there are various problems with iconographic and stylistic claims about petroglyph age estimation. In short, the dating of petroglyphs remains notoriously complex, and both microerosion and colorimetry deliver only results with substantial tolerance ranges.

Nevertheless, microerosion analysis (Bednarik 1992) has provided numerous credible results from much of the world, and is being applied very successfully in China, Europe, Saudi Arabia (see Figure 2), and many other regions. In this noninvasive method, the geometry of wane formation along the edges of crystals fractured during the production of a petroglyph is utilized. The widths of these micro-wanes, visible only under a binocular microscope (see OPTICAL MICROSCOPY), are a direct and linear function of age. The rate of their development needs to be calibrated to the environmental conditions of specific regions and for particular minerals. So far, only quartz and feldspar have been used in this method, and only comparatively erosion-resistant rock types are of relevance. The calibration curves now available from many climatic regions have suggested that the rate of solution is primarily a function of precipitation and therefore the need for calibration is expected to fade out progressively. The results obtained through microerosion analysis are reliable, as there is no potential contamination, and reversal of the underlying process is impossible. However, the precision of results is relatively coarse, with tolerances of about 20 percent to 25 percent being reported.

Figure 2 Relief percussion petroglyphs, dated to the Neolithic period, at Jabal al-Raat, Shuwaymis, northern Saudi Arabia.

Colorimetry of the ferromanganese accretions formed on petroglyphs is another method striving to establish “target dates” without physical intervention (Bednarik 2009). However, this approach promises little in the way of precision and has so far only been applied experimentally.

Interpretation of petroglyphs

Unless there is sound ethnographic information available, the determination of the meaning of petroglyphs or other rock art lies outside of proper science. Nevertheless, it is the approach favored by most archaeologists and therefore requires attention. All iconographic interpretation (see INTERPRETATION) of rock art involves *pareidolia*, the experiencing of meaningful patterns in random stimuli. Since modern beholders of such imagery lack the brain structure and composition, and therefore the perception, of its producers (Helvenston 2013), the modern observers cannot determine the emic meaning of supposedly figurative motifs. We can only function as human beings in the context of our societies here and now; we have no way of understanding the conceptual world of people thousands of years ago.

Neurologically, the process of etic interpretation of rock art is the imposition of imagery stored in the visual cortex over the signals the lateral geniculate nucleus (LGN) of the thalamus receives from the optic nerve (Bednarik 2016b). As much as 95 percent of excitatory, inhibitory,

or modulatory input in the LGN derives from the visual cortex, superior colliculus, pretectum, thalamic reticular nuclei, local LGN interneurons and other projections. The latter include feedback projections from the higher areas of the visual cortex of the inferotemporal cortex, where visual memory and imagery occurs, back to the visual cortex. Therefore what we see is determined mostly by our internalized model of reality, and the ontogenic experiences stored in the brains of earlier humans who created rock art can be assumed to have been dramatically different from ours. Moreover, the “interpretations” of rock art decipherers cannot be tested; they are freestanding, capricious claims and are therefore not scientific.

In pareidolic interpretation of rock art the beholder divines the meaning of a motif by first deciding subliminally whether it is aniconic or iconic. If elements of the figure or its overall form convey the impression of being depictive it is perceived as iconic. The decoding of the motif is initially by disambiguation of marks and textures on a rock surface. The production of iconographic forms is simply the intentional creation of features prompting visual responses to a signifier; it induces visual ambiguity deliberately. The human visual system is prompted to perceive an object where only marks and textures exist, through exploiting their visual ambiguity. This is the basis of all iconographic art: its elements are arranged and rendered in such a way that visual disambiguation experiences them as resembling objects, via pareidolia. Once an arrangement of paint residues or grooves on rock is perceived as intended to depict an object, the arrangement is scanned for confirmation that one of the options presented by the visual cortex matches it in adequate detail to pursue the correspondence further. In this process any disconfirming visual aspects tend to be disregarded or explained away as not deliberate or as badly executed, as being attributable to awkward materials or deficient skills, or to stylization, conventionalization, or schematization. At this stage of the process science, demanding the full consideration of disconfirming evidence, is discarded in favor of confirmation and autosuggestion. The beholder has latched onto a potential interpretation and now rationalizes accordingly. Finally, the detected image is scanned for

arbitrarily selected “diagnostic details,” rendering the process nonscientific.

Formal characteristics

Another favored way of characterizing petroglyphs is to create taxonomies of them by defining formal categories. Although such an approach is essential for the quantification of assemblages, for their comparative assessment, for statistics and the definition of cultural entities, there are also considerable difficulties with such approaches. The range of motifs of a site does not present an inherently consistent system akin to the periodic table of elements; it can only be divided by arbitrary classification. Moreover, co-occurrence at a site does not imply that the components of a corpus belong to a single tradition. On the contrary, major rock art sites tend to be accumulations featuring the residue of multiple traditions, often prompted by pre-existing imagery. Unless these are recognized and separated, any taxonomy of motif forms serves little purpose and may be quite misleading. There is a tendency of believing to detect stylistic regularities, which are then proffered as evidence of culturally cohesive characteristics. This tends to lead to the circularity of the argument that such perceived formal consistencies have been demonstrated, and that they therefore reveal cultural diagnostics.

These are not the only adversities in creating etic taxonomies of rock art. The arbitrariness of the process is evident when the practicalities are considered in detail. For instance, one of the common petroglyph motif types is the circle, but there are in fact literally countless variations of the circle found in rock art. At what point should one discriminate between a circle and an oval? Is a circle made by a male the same motif as one created by a woman? Is a large circle the same motif as a small, a horizontal the same as a vertical? Are two circles two motifs or one? What if one is placed inside another one? The possible variations and combinations are endless, and wherever the analyst draws boundaries, these will always be arbitrary. Such etic taxonomies can be expected to differ from emic classifications and interpretations. Therefore they only serve as loosely

descriptive tools, they cannot be analytically valid and their scientific utility is very limited.

Not only must archaeological taxonomy be considered arbitrary, we have no way of knowing how the *surviving* evidence relates to the *originally* created rock art. How much rock art has fallen victim to patination, exfoliation, rain water, frost shattering, insolation, sediment cover, erosion, consulting archaeologists, or whatever other taphonomic factors? In short, formal characterization of a corpus of petroglyphs is of limited utility; its principal expediency is in the field of rock art conservation (see CONSERVATION).

Other scientific approaches

An important part of characterizing petroglyphs is the study of their technology, that is, how they were created. This is based on the methodology of forensic science, as is most of scientific work with rock art. The tribology of petroglyphs has only been considered most recently (Bednarik 2015) and this work has led to the discovery of kinetic energy metamorphosis (KEM) products in several continents. Replication studies of petroglyphs are inevitably involved in the investigation of their production methods, and they raise issues of biokinetics, energy investment, and the quantifiable empirical effects of petroglyph creation. Combined with inquiries into the taphonomy of petroglyphs and the application of forensic methods, this area of research has emerged as the most productive in generating credible scientific characterization of petroglyphs.

Another important aspect of the science of rock art is conservation science, a field that has been developed especially in the past 40 years or so. In the case of petroglyphs, it involves a good understanding of the lithology and the weathering processes they are subjected to. These include the effects of natural moisture (meteoric, capillary, through condensation, etc.), and physical and biological weathering. Alleviating these threats is the ultimate purpose of conservation work, and a variety of techniques have been developed. However, it needs to be clearly stated that the greatest threat to any rock art by far is human intervention, be it by site visitation, professional vandalism of archaeologists, or the incidental

introduction of environmental change. Concerning the latter variable, the most obvious factors are anthropogenic climate change and the universal global reduction of precipitation pH (acid rain).

Recording of petroglyphs

Traditionally, the recording of petroglyphs has been accomplished by a variety of methods, such as freehand drawing, photography, rubbing or stamping, tracing on transparent sheets, and by casting with such substances as latex and wax. There are shortcomings or significant conservation issues with all of these approaches, and more satisfactory in terms of results are night photography, using low-angle (“strafing”) lighting to provide better depth to photographs, and photogrammetry (see DIGITAL PHOTOGRAMMETRY). In the latter method, precise measurements can be taken and 2D or 3D models can be created from orthophotographs. Recent developments in the area of computer vision-based photogrammetry (see COMPUTER APPLICATIONS IN ARCHAEOLOGY) have resulted in a simplified methodology of generating such models from standard photographs, processing these with dedicated software (Sanz et al. 2010; Plets et al. 2012). The results permit 3D manipulation of digitized products, rendering the documentation not only more dynamic and precise, but offering a tool for scientific dissemination of results and also for the management of petroglyph sites (López Fraile, Gómez García, and Caballero Klink 2016). These developments have already begun to revolutionize the recording of petroglyphs and introduced hitherto unimaginable precision.

Characterization of Pigments

H. H. MAREY MAHMOUD

Cairo University, Egypt

In ancient times, humans left their lifestyle marks in the form of rock paintings. Many of the cave paintings (e.g., in the caves of Altamira in Spain and Lascaux in France) represent different forms of simple handprints and wild animals. During the Paleolithic, humans used pigments available in their environment. Such pigments were inorganic minerals (earth pigments) and organic materials (soot or charred bones). The analytical investigation of ancient pigments is an important tool for understanding ancient materials, art history, and the development of technologies. Furthermore, the analysis of the painting materials helps in identifying a painting's technique and state of conservation before any restoration interventions. In the case of wall paintings, a number of analytical methods are regularly used. Microscopes (the optical, light-polarized microscope and the scanning electron microscope), elemental and microchemical analyses (by EDX and μ -XRF), and molecular analysis with μ -Raman and FT-IR spectroscopies are widely used.

Pigments in ancient Egypt

For decades, the ancient Egyptian pigments have attracted scientists and archaeologists. Pigment analysis is an important way of providing scholars with data on ancient materials and technologies. Pigments were used in ancient Egypt to decorate tombs, temples, coffins, pottery, and other funerary objects. Considered humanity's first synthetic pigment, Egyptian blue was a great technology used by the Egyptians for thousands of years. The main pigments used in ancient Egypt were of natural or synthetic origin. Earth minerals

and pigments derived from iron oxides were widely used in ancient Egypt. Red and yellow ochres (hematite, Fe_2O_3 ; goethite, $\alpha\text{-FeOOH}$) were used without interruption from the fifth dynasty (c. 2494–2345 BCE) to the Roman period in Egypt (El Goresy et al. 1986). For blue colors, the so-called Egyptian blue was successfully produced from the fourth dynasty on (c. 2613–2494 BCE). This pigment was made by mixing calcium salt (carbonate, sulfate, or hydroxide), copper compounds (oxide or malachite), sand (silica), and alkali flux materials (natron salts from Wadi Natrun, or soda-rich plant ashes). The final product is calcium copper silicate (cuprorivaite, $\text{CaCuSi}_4\text{O}_{10}$), a blue tabular crystal (about 15 μm to 30 μm in length). For green pigments, another form appeared shortly after the manufacture of Egyptian blue. Egyptian green is a multicomponent pigment, mainly of green wollastonite—a blue copper-, sodium-, and chlorine-bearing glass phase (Pagès-Camagna and Colinart 2003). For royal decorations arsenic-based pigments were used. Orpiment (As_2S_3), also known as king's yellow, was applied, with its shiny color, in wall decorations and coffins in ancient Egypt. Realgar (As_4S_4), with its red-to-red-orange color, was identified in the tomb of Thutmose IV (c. 1419–1386 BCE; El Goresy et al. 1986). In special cases, orpiment was added to ochre pigments in order to enhance the deep and shiny appearance of the color. The first evidence for these multi-pigmented layers in decorations was found in the Karnak temple complex (ruins of Hatshepsut, c. 1498–1483 BCE) and in the Deir el-Bahari temple on the west bank of Luxor, Egypt.

Another rare pigment, jarosite ($\text{KFe}_3^{+3}(\text{SO}_4)_2(\text{OH})_6$), was used to produce a pale yellow and was reported as a pigment in Egyptian contexts since the eleventh dynasty (c. 2133–1991 BCE). Furthermore, during the Ptolemaic and Roman periods in Egypt, green earths were used to decorate different monuments. These clay pigments are mainly based on the dioctahedral micas, celadonite, and glauconite. Earths of darker colors—usually called “sienna” and

“umber”—were probably used as pigments since ancient times. Their chromatic hues range from deep brown to reddish and greenish brown. They can contain admixtures of hematite and manganese (Mn III, Mn IV) oxides (Hradil, Grygar, and Hradilova 2003). Red lead (minium secundarium, Pb_3O_4) was found in Roman wall paintings in Egypt. It is one of the earliest artificially prepared pigments still in use until today. White pigments enjoyed extensive applications in ancient Egypt. It is believed that gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) or anhydrite (CaSO_4) may be used from the fifth dynasty on. On the other hand, calcium carbonates were used until the reign of Emperor Tiberius (14 CE to 37 CE). Another white pigment, huntite ($\text{Mg}_3\text{Ca}(\text{CO}_3)_4$), was used for the first time in the New Kingdom (time of Hatshepsut or Tuthmosis III, c. 1504–1450 BCE; El Goresy et al. 1986). Also, hydrocerussite ($2\text{Pb}(\text{CO}_3)_2 \cdot \text{Pb}(\text{OH})_2$) was reported to have been found in the Ptolemaic baths near the Karnak temple complex, from the time of Ptolemy III (246–221 BCE). Black pigments of vegetable (plant matters, soot) or animal (charred animal bone and ivory) origin were used in ancient times. The most important pigment was carbon black, and the only crystalline carbon used as pigment material was graphite. Soot is famous for its fine crystals and its homogeneity; when mixed with the paint medium, these crystals appear in the form of chains or fibers. Black pigments from mineral sources such as manganese oxides were already identified as ancient pigments. Pyrolusite (MnO_2) was found in ancient Egyptian wall paintings from the twelfth dynasty (c. 1991–1786 BCE) in Beni Hassan tombs of the El-Minia governorate in Egypt.

The analytical techniques

The analysis of wall paintings is affected by many factors: the small size of sample, the degradation processes, the multilayered structure, and the complexity of the mixtures (which have organic and inorganic compounds). The analyzing method for ancient materials should be micro or nondestructive, fast, sensitive, and multielemental.

Optical microscopy (OM)

The examination of painting materials usually begins with visual observations that are useful in providing data about the stratigraphy of paint layers, their microstructure, grain size, and colors and in detecting any impurities. Paint flakes and mounted cross-sections are commonly used for that purpose. Samples must be collected from hidden or seriously damaged areas. A small part of the sample is mounted in plastic peel molds. Then the sample is fixed in vertical position by using a suitable adhesive (e.g., Acryloid B72). The sample is then placed on the sticky side of the tape, so that its “sandwich side” sticks in “standing” position on the tape. Epoxy resins or acrylic resins are used to mold over the sample and to cover it completely. The resins are applied at room temperature for 18–48 hours. The resin must be transparent, have a short hardening time, and be resistant to cracking; and it is best if it does not react with the sample. The last step is the process of polishing in special machines that use silicon carbide paper to obtain a perfectly flat plane and a full cross-section (Derrick, Souza, and Kieslich 1994). Siddall (2006) published an important review of the application of polarizing light microscopy to the study of pigments, plasters, and mortars from the Roman age.

A blue-paint layer was collected from the festival temple of Tuthmosis III (c. 1504–1450 BCE, the eighteenth dynasty). Preliminary observations on the sample were performed using an Olympus SZ-40 stereomicroscope. Microscopically, the sample showed a coarse heterogeneous matrix with dark and light blue colors. Diluted Egyptian blue pigment is fine-textured and a large amount of glass is formed in its composition.

Scanning electron microscopy

Scanning electron microscopy is widely used to investigate morphology, microstructure, and chemical composition, especially when combined with an energy-dispersive X-ray microanalysis detector (SEM-EDX). This technique uses a focused beam of high-energy electrons to generate a variety of signals at the sample's surface. These signals include secondary electrons that produce SEM images or backscattered electrons

that give BSE images. In SEM technique, samples are usually covered with a conductive coating, most often of carbon or gold. In environmental scanning electron microscope (ESEM), no preparation of the sample is needed. With computer-controlled instruments, X-ray colored maps are produced by recording the number of X-ray photons for a fixed time at each point in the scanned area.

A blue-pigment sample was collected from the wall paintings of the mortuary temple of Ramesses III (Medinet Habu, Luxor). The mortuary temple of Ramesses III (Medinet Habu) is one of the largest memorial temples in Egypt that remain from the twentieth dynasty. It was built at the order of the Pharaoh Ramesses III (c. 1184–1151 BCE). The sample was studied with a JEOL JSM-840A scanning electron microscope equipped with an energy-dispersive X-ray (EDS). Figure 1 shows an elemental map of a polished cross-section of the sample; the map was obtained through backscattered electrons (BSE). Idealized crystals of cuprorivaite can be easily noticed within siliceous coarse matrix. The element disruption microanalysis of the sample indicates that the predominant elements are silicon, calcium, and copper.

Micro X-ray fluorescence spectrometry (μ -XRF)

For some fifty years, X-ray fluorescence spectrometry has been applied successfully to the study of cultural heritage materials. This technique is working without consuming the samples and enables qualitative and quantitative analysis. This method is based on the excitation of an inner-shell electron by an incident photon in the X-ray region. During the deexcitation process, an electron is moving from a higher energy level to fill the vacancy. Then the energy difference between the two shells appears as an X-ray emitted by the atom. The X-ray spectrum acquired through this process reveals a number of characteristic peaks. Finally, the energy of the peaks leads to the identification of the elements, while their intensity provides the relevant or absolute elemental concentration (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)).

A sample of the blue-paint layers was collected from the wall decorations of the mortuary temple of Ramesses III (Medinet Habu) on the western bank of Luxor. The micro-XRF spectrometer (SPECTRO, COPRA model) was used to analyze the sample. The microanalysis of the sample indicates that the predominant elements are copper, silicon, calcium, iron, potassium with traces of magnesium, and chromium. With the aid of a micro-Raman spectrometer, these results indicated the presence of cuprorivaite in association with other compounds of quartz (SiO_2), gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), calcite (CaCO_3), and halite (NaCl). As for pigment samples from ancient Greece, Aloupi, Karydas, and Paradellis (2000) reported the capability of X-ray-based analytical techniques to study such samples from wall paintings and ceramics in Greece and Cyprus. Also, Egyptian blue was found in the palace of Knossos, which goes back as far as to the third millennium BCE (Filippakis, Perdikatsis, and Paradellis 1976).

Micro-Raman spectroscopy

Raman spectroscopy is a microanalytical method that offered many advantages in the analysis of heritage materials. It is a form of vibrational spectroscopy that allows the identification of particles in the micron order. The identification is based on the molecular vibrational spectra of the samples, obtained through excitation with visible laser light (see RAMAN SPECTROSCOPY). In a micro-Raman spectrometer, the laser beam is focused by means of microscope objectives that employ a backscattering configuration (Perardi, Zoppi, and Castellucci 2000).

Red-pigment samples were collected from Roman overpaintings at Luxor temple in Upper Egypt that date from the reign of the Emperor Diocletian (r. 284–305 CE). Raman spectra were recorded using a triple-grating spectrometer (Dilor XY) in the red line excitation (632.8 nm). The laser was focused on the sample through the microscopic unit attached to the instrument. The μ -Raman spectrum collected on a red-pigment sample that was compared with the RRUFF Raman-Database confirmed that the main characteristic bands (at 226, 298 and 408 cm^{-1}) are for

Figure 1 Backscattered SEM image and an element distribution map obtained from a polished cross-section of the blue-pigment sample from the mortuary temple of Ramesses III (Medinet Habu, Luxor).

hematite (Fe_2O_3). Moreover, Raman microspectroscopic analysis was applied successfully to the study of paintings in the hypocaust in the Roman villa of El Ruedo (Almedinilla, southern Spain), built in the first century CE. The specimens studied were from the third and fourth centuries (Mateos et al. 2015).

Fourier-transform infrared spectroscopy (FT-IR)

Infrared spectroscopy has a wide range of chemical applications. It helps in the identification of both organic and inorganic compounds. In this technique, the unknown sample is irradiated by

an infrared beam (IR). Then certain wavelengths that indicate the presence of specific functional groups are usually absorbed by the sample (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)).

Pigment samples were collected from the monastery of Saint Anthony in Egypt. The origins of the monastery date back to the fourth century CE. FTIR-ATR spectra were collected using a Perkin Elmer spectrometer 400. In attenuated total reflectance (ATR) spectroscopy, the sample is placed in contact with a special crystal (e.g., diamond, zinc selenide, germanium). The spectrum obtained on the green-pigment sample showed that green earths can be distinguished in the 3,400–3,700 cm^{-1} and 950–1,100 cm^{-1} range. Glauconite is characterized by broad peaks in the 1,100–944 cm^{-1} region.

Color measurements

Color measurements are applied to the study of painted objects for many purposes. They help in the registration of characteristic reflectance spectra. Measuring devices such as spectrophotometers and tristimulus colorimeters provide a numeric expression of the color that is based on mathematical conversions of tristimulus values. Also, measurement reproducibility is greatly affected by surface uniformity, which is significant because surfaces of wall paintings tend to be quite irregular. One of the most common numeric systems for expressing color or color difference is the CIELAB notation.

Pigment samples were collected from wall paintings in Egypt. The spectra were obtained in the visible wavelengths domain (400 to 700 nm) with the help of a Miniscan® XE Plus spectrophotometer. Chromatic values are expressed as color coordinates in the Commission Internationale de l'Éclairage (CIE) $L^*a^*b^*$ Color Space 1976 system. The reflectance spectra of the blue-pigment sample showed a slope at wavelengths higher than 650 nm, which indicates the presence of Egyptian blue. The green pigments sloped sharply at wavelengths higher than 630 nm, with values then continuing to increase after this wavelength. Some chromatic changes of the blue pigment in the form of green colors can be observed through a small shift (at 520 and 580 nm). The reflectance

spectra of the red pigment (hematite) showed a sharp positive slope at wavelengths higher than 600 nm, while goethite showed a slope lower than 600 nm. The reflectance spectra allowed researchers to identify and differentiate the colors of the samples and to detect any chromatic alterations.

Chemical Mapping

DAVID A. ATWOOD
University of Kentucky, USA

Definitions and introduction

The seemingly simple term “chemical mapping” actually encompasses a broad range of potential information that can be synthesized into a conceptual information-rich “map”. A chemical map for an artifact could contain chemical information such as composition, phase, and surface features that would translate into a multidimensional context for the object that includes geographical location, date, origin, function, and value. As may be imagined, chemical maps could include a wide range, with a nearly limitless variety of information. An important requirement, a boundary condition, is that chemical maps should provide an opportunity for new archaeological knowledge, interpretations, and insights. In this context, “chemistry” is synonymous with “chemical analysis”. This will effectively circumscribe “chemical mapping” with easily understood rules and boundaries (Guralnik 1984). This will be facilitated by a utilitarian classification of chemical substances having specific, albeit substantially overlapping, analytical techniques. The resulting data, for example, the concentrations of selected elements across an area of interest, would provide the basis of the chemical map. Chemical substances can be suitably subdivided into five interrelated classes, listed here with brief explanations and examples:

1. *Elements*: Fe, Co, Au, Pb, transition metals, lanthanides, and actinides.
2. *Molecules*: For example, indigo as found in Maya Blue pigments, where the indigo molecules form non-covalent or non-ionic bonds to the host palygorskite. The resulting composite material may be classified as a compound or possibly a mixture.
3. *Compounds*: Must have definite composition, represented by a molecular and/or empirical formula. Indigo, $C_{16}H_{10}N_2O_2$, is a molecular compound; palygorskite, $(Mg,Al)_2Si_4O_{10}(OH) \cdot 4H_2O$, is a compound but not a molecule; the rare white pigments laurionite, $Pb(OH)Cl$, and phosgenite, $Pb_2(Cl_2)CO_3$, have repeating units to form an extended structure that is not molecular.
4. *Mixtures*: Physical combinations of any proportion of elements, molecules, and compounds, where no chemical transformation takes place and the original identity of each is maintained; the chemical analysis can be similar to the analysis of the pure element, molecule, or compound.
5. *Materials*: This is the broadest category and used interchangeably with “solid-state” materials, whether organic (freshly-prepared gram quantities of indigo with varying levels of purity), inorganic (comprising “non-living” constituents such as galena, PbS), or biological (protein aggregates and oligosaccharides arranged by covalent bonding into large, cyclic tertiary structures).

Each chemical substance in this classification system will have a very large collection of applicable analytical characterization techniques with significant overlap and commonality, not unexpectedly, among the substances. Only three of the chemical substances are necessary to develop a useful definition for chemical mapping; these are *elements*, *compounds*, and *materials*. The general classification system and the simplification to three chemical substances will provide greater clarity within this article.

With three distinct solid chemical substances established, the fundamental definition of chemical mapping would combine the conventional geographical definition of “map” with the scope that “chemistry” encompasses. Webster’s Dictionary provides the necessary definitions (Guralnik 1984). The term “chemical” means of, or having to do with, chemistry. In turn, “chemistry” can be understood as the science that focuses on

the chemical elements (the Periodic Table), the compounds formed by the elements, and the associated solid-state materials. Seeking clarity from the night sky, *elements* have the same relationship to *compounds* that stars have to constellations. *Material* simply indicates the solid forms of elements and compounds. One of the great strengths of chemical analysis in relation to archaeology is that fundamental properties, atomic structure, for example, form the basis of most chemical analysis techniques. For example, XRD can be applied to almost all solid substances; archaeological meaning is obtained by combining and interpreting the analytical results with contextual information.

Within the field of archaeology, therefore, “chemical mapping” means the identification of chemical elements, compounds, and materials associated with an artifact, including trace quantities at part-per-million (ppm) levels. The elements become the stars, the compounds become the constellations. Like the unique arrangement of stars within constellations (created by human imagination), the presence and arrangement of elements within a compound or solid material can have additional meaning. In archaeology, this additional meaning can be knowledge and understanding about age, provenance, history, usage, relocation, and other contextual variables organized and understood through human imagination and experience. With continuing fundamental and technological advances, chemistry will become more integral to archaeology, and the scientific study of the life and culture of ancient peoples.

The natural and physical sciences are replete with techniques that can identify atoms and molecules in solids, liquids, and gases. Thus, it will be important and necessary that the term “chemical mapping” indicates the type of information being sought from the artifact under consideration. As might be imagined, based on the foregoing description, a wide range of subjects have been incorporated into chemical mapping. Some specific, representative subjects, combined with chemical mapping, will be described in subsequent sections of this article. In the meantime, two examples will demonstrate the most direct use of chemical mapping in a descriptive title: “Chemical Mapping of Paleontological and Archeological Artifacts with

Synchrotron X-Rays” (Bergmann, Manning, and Wogelius 2012) and “Chemical Mapping of Basalt Flows at Paleolithic Sites” (Goren-Inbar, Perlman, and Heimann 1986). Both of these titles provide a very useful precedent for chemical mapping publication titles: “Chemical Mapping of [Artifact Description] with [Analytical Technique]”.

In many cases, it is unnecessary to employ “chemical mapping” in a descriptive title, as demonstrated by: “Investigation of Neolithic ceramic pigments using synchrotron radiation X-ray diffraction” (technique abbreviation, SR-XRD). The analysis of artifacts with SR is a growing area of applied chemistry, and newly available techniques, generally abbreviated SR-XYZ (e.g. SR-XRF), are being applied to archaeological analyses. A large and expanding number of techniques can determine the elements, compounds, and materials within an artifact.

Mapping elements and compounds

A common analytical methodology is to map the elements of interest in a given area. This is exemplified by the mapping of elements in urban areas (Allen et al. 2011). Samples are obtained, digested, then analyzed by techniques that provide element concentrations, such as X-ray fluorescence spectrometry (XRF), inductively coupled plasma atomic emission spectrometry or mass spectrometry (ICP-AES or ICP-MS). Regarding the value of these elemental analysis techniques, the authors note: “These techniques are capable of determining up to 50 elements in a single analysis and have detection limits such that most elements can be determined and mapped at background concentrations” (Allen et al. 2011). Elements that can be identified include As, Cd, Cu, Mn, Ni, Pb, Se, and Zn.

Another modern-day example of chemical mapping utilizes a portable gas analyzer (developed in 2005) to characterize the gases emanating from a fumarolic field (0.045 km²). The output rates and relative ratios of CO₂/SO₂/H₂S were determined with 3,000 real-time measurements to produce a three-dimensional map of gas concentration from source to eventual dissipation.

Neutron activation analysis (NAA) was used to map 25 selected elements present in two very old basalt flows comprising an upper layer (233,000 years BP), an intermediate layer containing a Paleolithic site of great interest, and a lower layer (800,000 years BP). The authors indicate that “Those [samples] chosen for analysis represented all of the stratigraphic units described by the geologists, but with only 32 samples, the study must be considered exploratory. Nevertheless, it was hoped that it would serve to answer such questions as whether different units could be told apart and what further work would be needed to obtain a more comprehensive mapping” (Goren-Inbar et al. 1986). The study confirmed that element distributions obtained by NAA could be used to distinguish between two different basalt flows. Elements with a high crustal abundance were found at similar concentration levels (Ca, Fe, K, Na, Ti) in both basalt flows. However, the majority of the elements selected for analysis were at parts-per-million (ppm) levels. The upper and lower basalt flows did, indeed, have substantially different element distributions (within the ppm range).

Synchrotron radiation mapping techniques

An exceptionally wide range of archaeological artifacts have been analyzed, non-destructively, at various SR light sources around the world. The primary limitation with this technique is that artifacts must be transported to the SR facility. However, there is a long list of advantages, such as short analysis times (~1 min), small sample size or area, ability to analyze heterogeneous samples, high-intensity, tunable photon energy, high photon flux, high resolution, non-destructive, and the ability to process a large number of samples or sample multiple sites on a single object to provide statistical data.

SR dramatically improves the capabilities of existing X-ray techniques, such as X-ray powder diffraction (now abbreviated SR-XRD), X-ray fluorescence (SR-XRF), X-ray absorption spectroscopy (SR-XAS), near-edge X-ray absorption fine structure (SR-NEXAFS), X-ray absorption near-edge structure (SR-XANES),

X-ray photoelectron spectroscopy (SR-XPS), and others. Improvements are also observed for spectroscopic techniques like infrared absorption (abbreviated SR-IR), Raman scattering (SR-Raman), and many others (United States Department of Energy 2005). Although there are many techniques, they can be simply categorized as spectroscopy, scattering, and imaging.

SR-XRD was used to identify the mineral or material phases of black, red, and white pigments on the surface of Neolithic (~6300 BP) pottery sherds in much shorter times (30 s) compared with conventional XRD (hours) (Bugoi et al. 2008). The SR required only minute amounts of sample, so that a large number of samples could be analyzed. A small amount of material was removed from an unobtrusive location on a pottery sherd, sufficient to cover the backing tape on a 3-mm diameter 36-cell sample holder. The analyses produced very sharp diffraction patterns to unequivocally identify black jacobite (Fe_2MnO_4), magnetite (Fe_3O_4), and red hematite (Fe_2O_3). White pigments based on calcium silicates with high crystallization temperatures were also identified: diopside ($\text{CaMgSi}_2\text{O}_6$), augite ($((\text{Ca},\text{Na})(\text{Mg},\text{Fe},\text{Al})(\text{Al},\text{Si})_2\text{O}_6)$), and hedenbergite ($\text{CaFeSi}_2\text{O}_6$). The presence of white calcite (CaCO_3) was ascribed to post-burial deposition. Based on the outcome of this chemical mapping study, in the form of high-quality XRD patterns (the chemical analysis) across many samples (the mapping), the authors gained definitive information about clay composition, kiln atmosphere (several samples implied an unusual carbon monoxide-rich reducing environment based on the maintenance of magnetite during the firing process, although most samples were rich in hematite, Fe_2O_3 , indicating a typical oxidizing atmosphere), and the temperature reached (the presence of jacobite indicates a firing temperature of about 1,000 °C). Additionally, local sources were used for most of the minerals, but Mn-containing jacobite is uncommon and difficult to find. This led the authors to conclude: “This suggests that the Neolithic people specialized in gathering minerals from the surface of manganese mineral deposits and used them in producing black-decorated ceramics fired at high temperatures” (Bugoi et al. 2008).

Conclusions

As demonstrated in the few examples described in this article, chemical mapping takes many forms, but in all cases a chemical substance is analyzed and the resulting data are processed and interpreted to obtain new, often unexpected (as in the presence of jacobsite, Fe_2MnO_4 , in Neolithic pottery sherds) archaeological knowledge. The use of synchrotron-based characterization techniques will continue to grow in the coming years and begin to accelerate the amount of archaeological information already steadily increasing with each passing year.

FURTHER READINGS

Chemistry in Archaeology

RUTH ANN ARMITAGE

Eastern Michigan University, USA

Chemistry is often referred to—at least by chemists—as “the central science” because of its position between physics and the life sciences. On one end of the chemical spectrum is physical chemistry, vital to understanding the processes involved in spectroscopic methods, while the biochemistry at the other provides the molecular basis of DNA and proteins. Thus chemistry is also central to archaeological science, playing a part in nearly every area covered by this *Encyclopedia*. Chemical analysis—elemental, isotopic, and molecular characterization—is arguably the most widely known connection between the seemingly disparate fields. More than just analysis, chemistry is also the study of changes in matter. Chemical processes, particularly oxidation, have profound effects on archaeological materials. Light, particularly that of ultraviolet wavelengths, induces chemical changes to fragile organic materials like textiles and paper, leading to fading and loss of structural integrity. Even some prospection methods rely on the presence of chemical species that form when people interact with the environment. Dating methods that rely primarily on physics—radiometric dating in particular—require an understanding of the chemical composition and possible changes to the material during deposition. The role of chemistry in archaeology reaches far beyond what can be addressed here. This briefest of summaries highlights only the most prominent aspects of archaeological chemistry and will neglect much; the reader is directed to the References and Further Reading.

The maturing field of chemistry and the infancy of archaeology both trace to the Age of Enlightenment, and in many cases begin to overlap soon thereafter as the eminent scientists of the day sought to understand the newly discovered

materials of the past. While Sir Humphry Davy's investigations into the composition of the pigments from Pompeii and Herculaneum may be the best known early application of archaeological chemistry, others before him applied gravimetric analysis to the compositions of metal artifacts in order to better understand the technologies of the ancients and even to try to reproduce them. An overview of the history of chemistry relevant to archaeology can be found elsewhere (Pollard, Heron, and Armitage 2016). In the twentieth century, instrumental methods, which are generally less labor intensive and in some cases nondestructive, mostly replaced the classical wet chemical analyses, albeit at the cost of some precision and accuracy.

The study of the exchange of materials, and thus the determination of their origin, is a more complex application of chemistry that seeks to answer questions of past human behavior beyond those of technology. The variations in usage of the terms “provenance” and “provenience” aside (Price and Burton 2011), the general idea is that the elemental composition of an object should be consistent with that of the geochemical source of origin. This provenance postulate can only be true if variations in elemental composition *within* a given source are smaller than the elemental variations *between* different sources. Ideally, it would be possible to “match” an object to its source, though really one cannot prove such a thing, only that an object is *not* associated with a source that is significantly different. Geochemical provenancing works best for objects made from unaltered natural material, like obsidian and some stone; in ceramics and metal artifacts, using elemental analysis to determine the source of the clay or ore may be complicated by mixing of raw materials from different sources. Quantitative measurements of multiple elements must be compared in provenance studies, so the preferred analytical techniques for such studies include neutron activation analysis (NAA), inductively coupled plasma mass spectrometry (ICP-MS), ICP atomic emission spectroscopy (ICP-AES, also called optical emission spectroscopy or OES),

DOI: 10.1002/9781119188230.saseas0087

and X-ray fluorescence (XRF) spectroscopy. Atomic absorption spectroscopy, once a standard method, is only for sequential analysis of elements, and is not widely used in modern provenance studies. Many resources exist on geochemical analysis for provenance determination that provide further details (Glascok 2002).

Elemental analysis alone cannot determine the source of origin for all materials, particularly those that undergo recycling like metals and glass. In these cases, and in similar studies of human mobility, isotopic ratios of heavy elements have proven useful. While all atoms of a given element have the same number of protons, isotopes of the element differ in the number of neutrons present. Each isotope has a different mass equal to the sum of the numbers of protons and neutrons, and a mass spectrometer (usually ICP-MS specially configured for high mass resolution and high precision measurements) can be used to quantify each of the isotopes of interest. The isotopes of strontium vary in their geologic distribution, so the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio in human teeth, for example, can be compared to local values to determine if a person was born in a different location from where he or she died. Strontium isotope studies have been widely applied to human remains as well as many other archaeological materials. Lead isotopes have been used to define ore fields and have shown utility in sourcing metal artifacts from around the world, and they, too, are applicable to a variety of objects. Isotopes of neodymium are useful as indicators of the source of sands used in the manufacture of glass. Combining measurements of multiple isotopes (e.g., Sr and Nd for glass) or with other analyses is often the best approach for such provenance studies.

Provenance determination has also been applied to organic “minerals” like amber and jet recovered from archaeological contexts. Fourier transform infrared spectroscopy (FTIR) has been used extensively to differentiate Baltic amber from other sources, which allows archaeologists to better understand trade routes for this organic gem across Europe in ancient times. FTIR and Raman spectroscopies provide information about molecular structure based on how covalent bonds vibrate when they absorb or scatter infrared and visible wavelengths of light. The two methods are complementary and can be used for the identification of both organic and

inorganic molecules. Additionally, both methods can be made portable, can be integrated with a microscope for work with small samples, and are generally considered noninvasive methods. Raman spectroscopy is widely used in the identification of inorganic mineral pigments in manuscripts and in wall and rock paintings. Due to the intensity of the laser source, fluorescence from organic molecules can sometimes mask the Raman spectrum. Organic colorants, particularly red anthraquinone compounds from madder and cochineal, can be identified in situ in natural textiles with the addition of nanoparticle substrates for surface-enhanced Raman spectroscopy. There are many comprehensive reviews on the uses of Raman spectroscopy for archaeological applications (e.g., Bersani et al. 2016). More frequently, identification of organic dye colorants present in archaeological textiles is accomplished by extracting the color into a solution which is then separated using high-performance liquid chromatography (HPLC), with the molecules detected as they elute from the column often based on how the molecules absorb ultraviolet and visible (UV-vis) wavelengths. MS, described above as a method for elemental analysis, can also be used to identify organic molecules, and so can serve as a detector in chromatographic separations as well as forming a *hyphenated method* (e.g., HPLC-MS). Molecules must be *ionized*—given a charge—for mass spectrometric analysis. *Soft ionization* methods, like electrospray ionization (ESI), provide information on the molecular mass of a substance and are often used in tandem with HPLC. For separating volatile compounds (or those that can be made volatile through chemical derivatization), gas chromatography (GC) is preferred. When GC is coupled to MS, the gas-phase molecules are ionized and fragmented with a *hard ionization* method like electron impact (EI) ionization as they elute from the column. The molecular ions or ionized fragments are characterized based on their mass-to-charge ratios, with the fragmentation pattern that results from hard ionization serving as a kind of “molecular fingerprint” for identification.

The origin of petroleum products can be determined using gas chromatography mass spectrometry (GC-MS); the relative amounts of various hydrocarbons differ depending upon the source, even providing a link to the biological

origin of the deposit. In archaeology, such studies have been applied to determining the sources of bitumen in adhesive residues on Near Eastern ceramics and Egyptian mummies. Molecules that originate from specific biological contexts are called *biomarkers*. While they were originally used by geologists to identify and differentiate petroleum deposits, biomarkers have revolutionized chemical analysis that seeks to understand human activities in the past (Evershed 2008). Using GC-MS to separate and identify biomarkers like abietic acid and retene, it is possible to identify resins as well as the pyrogenic products pitch and tar that are made from them. Lipids preserved within the ceramic matrix of cooking vessels may also serve as biomarkers that are indicative of specific foods that were consumed in the past. Residues from food preparation can also be preserved in earthen and plaster floors, indicating areas of food preparation and consumption, thereby shedding light on past human activities (Pecci, Barba, and Ortiz 2017). Identifying such biomarkers requires significant chemical preparation, from extraction of the residues into appropriate solvents to derivatization (chemically reacting fatty or resin acids to produce volatile methyl esters or trimethylsilyl ethers and esters), and then finally separation and identification by GC-MS. When identifying biomarkers, it is critical to always consider the archaeological context, as not doing so runs the risk of drawing conclusions that are not reasonable for the time and place!

In the case of lipid biomarkers, isotopes again provide a way to differentiate residues that cannot be distinguished based solely on their molecular composition. In organic molecules, the stable (i.e., not radioactive) isotopes of importance are those of hydrogen (^1H and ^2H , often called deuterium), carbon (^{12}C and ^{13}C), oxygen (^{17}O and ^{18}O), and nitrogen (^{14}N and ^{15}N). While the electrons in an atom are gained and lost the same way in a chemical reaction regardless of the mass of the nucleus, the energy required for the reaction to occur is higher for a heavier isotope relative to a lighter one, meaning that the product of the reaction will be enriched in the lighter isotope and depleted in the heavier one. This is called the *kinetic isotope effect* and explains why C3 plants that photosynthesize with a more complex set of chemical reactions show more *isotopic fractionation* than C4 plants that fix carbon more

efficiently. Fractionation is expressed as a ratio of ratios, comparing the ratio of the heavier to lighter isotopes relative to that of a standard. For carbon, this yields a $\delta^{13}\text{C}$ value in parts per thousand (per mille, ‰). Lipid residues in ceramics are generally dominated by palmitic and stearic acids ($\text{C}_{16:0}$ and $\text{C}_{18:0}$, respectively), which are both saturated fatty acids and by themselves are not particularly diagnostic. However, it is possible to include isotopic analysis with GC-MS, by way of gas chromatography combustion isotope ratio mass spectrometry (GC-C-IRMS), where each component from the GC is combusted to form CO_2 , which can then be used to measure the $\delta^{13}\text{C}$ value of that component. Because adipose fat and milk fat stem from different metabolic processes, their $\delta^{13}\text{C}$ values differ even when their lipid content appears quite similar, so GC-C-IRMS can differentiate between residues deriving from these sources, and thus the relative input of the different sources in ancient diets.

IRMS on light elements is widely used to study ancient diet, based on the idea that chemically, and therefore isotopically, you are what you eat (to a certain extent). In general, the $\delta^{13}\text{C}$ value measured for collagen, a protein preserved in bone, can differentiate between individuals with a diet rich in C3 versus those who consumed primarily C4 plants, which in North America is indicative of the introduction of maize. Nitrogen isotope fractionation is affected by trophic level, or position in the food chain, as the amount of ^{15}N increases up the chain from herbivores to carnivores. Measuring the $\delta^{15}\text{N}$ values of bone collagen can indicate whether or not ancient people ate seafood, which differs markedly from terrestrial food animals in $\delta^{15}\text{N}$ values. Hydrogen and oxygen isotope ratios are linked to the composition of locally available water sources. The $\delta^{18}\text{O}$ of human teeth, formed in childhood, can be used like strontium isotopes as indicators of outliers among a local population, showing individuals who moved to the area later in life (Pollard et al. 2016). Oxygen isotopes are also used in paleoclimate reconstruction. Evaporation and condensation of water, through physical changes of state, result in fractionation, with ^{18}O -rich water evaporating less readily and condensing more readily; the $\delta^{18}\text{O}$ values for water in polar ice cores decrease as a function of cooler temperatures. Hydrogen isotopes are similarly affected.

Bone collagen is perhaps the most important biomolecule in archaeological chemistry. Used in isotopic studies as above, it is also collagen that is preferred for radiocarbon dating of bone. Well-preserved bone collagen has been used to indicate the likelihood that reliable ancient DNA persists for analysis. Most recently, collagen has become the target for proteomic analysis, where the amino acid sequences of a protein are used to identify an organism down to the species level in many cases. Fragments of bone are often too small to identify visually; with proteomics, the collagen from such fragments can be extracted, then digested with enzymes to make shorter chains of amino acids (called peptides), and finally characterized with MS to yield a sequence unique to the organism. A new and promising approach to archaeological proteomics is called “zooarchaeology by mass spectrometry” or ZooMS (Collins et al. 2010). Small fragments of bone and egg shell can be identified with ZooMS, yielding information about exploitation of various food sources. Other proteins, like caseins from milk and hemoglobin from blood, that are preserved in residues can be characterized by proteomics methods as well. Combining several chemical methods, like residue analysis and proteomics, is often the best approach for small and fragmentary samples (Pollard et al. 2016, Chapter 13). Without the biomolecules preserved in a fragment of a finger bone and a few teeth, we would not know that the Denisovans even existed!

The future of chemistry in archaeology is nearly limitless, as analytical methods become more widely available, more user-friendly to the nonspecialist, less destructive to materials, and even field-portable. Even today, large datasets of elemental analyses and geographic information systems (GIS) are being put into combined use for understanding the movement of materials like metals across landscapes in ancient times (Hsu et al. 2016). Biomolecules that were once thought to be too fragile to survive will continue to provide new insights into human diet and resource exploitation thanks to advances in protein MS. MS itself has even undergone a revolution in how organic molecules both small and large can be ionized. Today it is possible to rapidly and without any extraction or sample preparation identify small molecules like dye colorants and food biomarkers in and on archaeological materials,

and often in such a minimally destructive manner that the materials can also be dated (Armitage and Jakes 2015) or preserved for future study. Hand-held portable instrumentation that is already commercially available allows archaeological scientists to collect both molecular and elemental information on objects in the field, and advances in miniaturization may yield portable techniques not yet considered possible.

This optimism for the future of chemistry in archaeology must also be tempered by the fact that the application of chemical analysis to ancient materials can never be presumed to be straightforward and simple. Methods developed for clinical analysis of fresh samples may be wholly inappropriate for ancient materials that have undergone myriad chemical and physical changes through time. As archaeologists cringe at the Hollywood depictions of Indiana Jones and his ilk, so too do chemists lament what passes for chemical analysis in the popular media, where magical boxes instantaneously produce not just results, but data interpretation and conclusions. The increasing prevalence of “point-and-shoot” instrumentation, particularly portable XRF spectrometers, has resulted in significant anxiety about the quality of data being published (Speakman and Shackley 2013), as well as whether users are aware of the limitations of both the method and the provided software (Shugar 2013). It is important to understand as much as possible both the nature of the materials and the capabilities and limitations of the analytical techniques before undertaking any analysis. As an example, analytical methods like XRF measure primarily the surface rather than the bulk composition of an object, due to the physics of the absorption and emission of the X-rays. For metal objects, analytical results can be influenced by surface corrosion as well as by enrichment or depletion of alloying metals at the surface. Selecting suitable samples and using proper techniques for their preparation is also essential. The importance of using traceable standard reference materials and applying appropriate calibration methods cannot be overstated. It is critical, too, that chemistry in archaeology be done not just in a scientifically responsible manner, but that it be driven towards generating data that will in some way address social, political, and economic questions about ancient people. Only then is chemistry really

useful to anthropological archaeologists who are seeking to understand culture and human behavior through material remains.

Chert, Silex, and Obsidian Sourcing

ADRIAN L. BURKE

Université de Montréal, Canada

Archaeologists regularly find materials (e.g., minerals, pigments, metals, shell) on their sites, either in raw form or transformed into artifacts, that cannot be found in the local environment. Finding the geologic and geographic source or provenance of these raw materials can often be the key to understanding the territories exploited by groups in the past, or trade and exchange that took place between different societies. Finding the mines or quarries of these materials is also an essential element in exploring ancient technological knowledge and reconstructing the steps required in the production of certain artifacts. A detailed analysis of the sources of the raw materials often leads to better understanding of the choices (performance, durability, sharpness, transport cost) made by humans and their ancestors.

Research on the sources of chert, silex, and obsidian (CSO) has exploded since the 1970s. One reason is the fact that chipped stone tools are the oldest artifacts of human or hominin manufacture recovered on archaeological sites around the world. Stone tools are also very well preserved and therefore offer a unique insight into early human behavior. The increase in research specifically on the sources of stone tool raw materials is also due to the rapid increase in the access to various instruments for the geochemical analysis of these rocks and minerals. Archaeologists today have many analytical tools at their disposal to better characterize the rocks, such as CSO used to make tools and decorative objects in the past.

CSO are all siliceous rocks that break conchoidally. These clastic properties, as well as their hardness and ability to maintain an edge, are what have made these materials useful to humans for thousands of years. Chert is a siliceous rock that

can be formed in various geologic settings, but is usually sedimentary in origin. Chert is the most inclusive term, and can include chalcedonies and jaspers. The term chert is used mostly in North America. Silex is the term used primarily among non-English speakers for flint. Silex or flint is also of sedimentary origin and can be found as nodules replacing chalks and limestones. The formation and diagenesis of limestone-hosted cherts and flints is not completely understood and there is significant overlap between cherts and flints in their geologic origin as well as their physical and chemical properties (Fröhlich 2006; Luedtke 1992). Obsidian is a volcanic glass. In terms of its geochemistry, it can be classed as a rhyolite, which makes it quite different from chert and silex/flint (Poupeau, Le Bourdonnec, and Bellot-Gurlet 2014; Shackley 1998). Several other siliceous rocks have been used in the past to manufacture tools and decorative objects (e.g., quartzite, rhyolite, agate); the techniques described below apply to the study of all sources of siliceous rocks.

Sources

Archaeologists define a source of raw material as a geologic outcrop or a secondary deposit of material (e.g., river cobbles, glacial till). Evidence of past quarrying or mining is not always obvious at these sources of materials. If people have used cobbles from a river, the only evidence might be the cobble cortex still present on tools or production waste like flakes. Paleolithic quarries are in fact extremely rare due in part to the soft nature of the limestone or chalk bedrock and the time that has lapsed since their exploitation. In general, it is via the workshops where people transformed the raw materials that we can often discover the original geologic source of a material. By the Neolithic period, people were excavating mine tunnels to extract silex/flint at places like Brandon, England, and Spiennes, Belgium. Here, specialists chipped and ground the silex into axes for local use, and also for export and trade across western Europe. In many cases,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0088

the quarrying activity of successive generations destroys the evidence of previous quarrying or mining activity. The extensive piles of debris, mostly flakes and low-quality host bedrock, are the best indicators that a source of CSO has been used over many generations. Ancient quarries are also notorious for not being easy to date, since there are rarely any diagnostic artifacts found among the millions of pieces of debris.

Where an actual quarry or mine can be identified, the archaeologist can clearly see how materials were selected and how the gangue was rejected. This helps to narrow the variability of the raw material source at the geologic outcrop. The material selection will also help to understand technological choices made by ancient flintknappers and stone workers. In many cases, however, clear evidence of a quarry is lacking and the archaeologist has to either focus on the workshops close to the geologic outcrops, or carry out geoarchaeological fieldwork using bedrock or surficial geology maps to identify the most likely formations and member (see *GEOARCHAEOLOGY*). A source in this case becomes a geologic formation that can often cover many square kilometers. In the case of obsidian flows, these can often be differentiated in the field, but they can also cover large areas.

Characterizing a source of CSO

Once a source has been identified, the raw materials need to be characterized. In the case of rocks and minerals, this usually begins with thin-section petrographic analysis. This is the traditional geologic approach to characterizing rocks and minerals, and is the best method for identifying any characteristic fossils, minerals, or structures in the rock (e.g., Eley and von Bitter 1989; Reedy 2009). All of these petrographic characteristics help to narrow down the source in terms of a member or bed within a formation. This also helps to understand the mechanical characteristics of the material that may influence the transformation or performance of the material (e.g., cleavage, foliation, joints). Obsidian is a glass and therefore does not have a crystalline structure. For this reason, petrographic thin sections are not often used in characterizing obsidians. Petrography

can help nonetheless in identifying phenocrysts or other distinguishing aspects of an obsidian.

Once the petrographic analysis has been completed, the next step is to characterize the source material using a geochemical or imagery technique. A number of instruments and techniques can be used to characterize CSO, and most sourcing studies combine a number of complementary techniques. These are constantly evolving and the field of archaeological science has to adapt to these new techniques with their various limitations and advantages. The most common instruments and techniques are described below, but first it is important to address the issue of sampling.

Sampling and sourcing studies

Perhaps the biggest challenge in the field of sourcing CSO is sampling. How does one sample a source in order to have a representative sample that covers the geochemical or petrographic variability of that source? In some cases, like that of an obsidian flow, the geochemical variability may be minimal, allowing the sampling to be more limited. In other cases, like that of chert formations that extend for kilometers, this can be much more difficult to assess in the field. Silex or flint is usually present as nodules in beds, and specific beds were targeted in the past for exploitation. This can also help to narrow the sampling strategy. Typically, the geochemical characterization of a source will have to proceed in steps. First, one does an initial sampling of a formation or member along and across strike. These samples are then analyzed to assess the chemical variability of the raw material source. If this variability is high for several elements, then it may be difficult to differentiate which specific part of a formation was used unless this is clearly related to a specific location along strike (related to a basin, for example) or across strike (a specific bed or member within a formation). The same problem can arise if the chemical or petrographic variability is minimal. In this case, it might be impossible for an archaeologist to identify a source more precisely than a very large area several square kilometers in extent that is covered by a geologic formation.

Techniques and instruments used to characterize CSO

The techniques used to characterize CSO can be divided into two categories: chemical and imagery. Chemical techniques analyze either the chemical composition of the rock and its constituent minerals (major, minor, and trace elements) or specific isotopes. Imagery techniques create images of the rocks and minerals at high magnification using the interactions of electrons and the surface of the material. Petrography is an imagery technique that is based on transmitted light microscopy using polarized light and filters. All of these techniques make use of instruments that are housed in specialized laboratories. In some cases, like the scanning electron microscope combined with an X-ray spectrometer, chemical and imagery techniques can be combined in one instrument. Some techniques are destructive, requiring samples to be reduced to powder, others are microdestructive, such as those that use a laser to remove a tiny sample from the surface, and other techniques can be applied in a completely nondestructive fashion.

Most instruments can produce qualitative and quantitative data, and how these are used depends on the research question being addressed. In addition, each instrument has different levels of precision, accuracy, and limits of detection. In terms of chemical characterization this can vary for each element being measured. The lack of international certified geochemical standards for CSO makes it difficult to develop reliable, interlaboratory tests for precision, accuracy, and limits of detection.

CSO have different levels of intrasource chemical variability which affects how an instrument will be applied to the analysis of samples and artifacts. Obsidian is the most homogeneous and an analysis taken anywhere on an artifact or hand sample will typically be representative of the whole artifact or geologic sample. On the other hand, cherts are highly variable even at the level of a hand sample. This is due to their sedimentary origin. As a result, when carrying out chemical analyses it is important to keep in mind this chemical variability and analyze more than one location on an artifact or geologic sample in order to counter what is referred to as the nugget effect.

The following instruments are those used most often for the sourcing of siliceous rocks in archaeology.

Neutron activation analysis

Neutron activation analysis (NAA) (see NEUTRON ACTIVATION ANALYSIS (NAA)) or instrumental neutron activation analysis (INAA) (see INAA AND MATERIAL ANALYSIS) has been used extensively for the chemical characterization of obsidian, and to a lesser extent chert and silex. It was one of the first techniques used to characterize obsidians and link geologic sources to artifacts found on sites (Griffin, Gordus, and Wright 1969; Renfrew, Dixon, and Cann 1966). It has the advantage of measuring a large number of elements simultaneously (>30), and has very low limits of detection for many elements (parts per million to parts per billion) such as trace elements and rare earths that are typically important for identifying the geologic source of a rock. The technique can be used in a nondestructive mode if the artifact fits in the polyethylene vial.

X-ray fluorescence spectroscopy

X-ray fluorescence spectroscopy (XRF) (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)) has also been used extensively for the chemical characterization of obsidian, and to a lesser extent chert and silex (Shackley 1998; 2011). It can be used nondestructively, and has the advantage of being able to analyze large artifacts that will not fit in other instruments. It has proven particularly well adapted to the analysis of obsidian due to the homogeneous, noncrystalline (glass) structure of obsidian. The advent of portable XRF (pXRF) (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)) has added an important new dimension to sourcing studies, giving the archaeologist the possibility of analyzing artifacts in the field or in a museum. This is especially useful where the artifacts cannot leave a country or a secure setting. The precision and accuracy of the latest XRF and pXRF instruments is excellent. Limits of detection for many elements are only at the 10s of ppm for most instruments, unless they are equipped with a powerful X-ray tube and a vacuum chamber.

Particle-induced X-ray emission

Particle-induced X-ray emission (PIXE) (see ION BEAM ANALYSIS (PIXE/RBS) and PIXE AND MATERIAL ANALYSIS) is similar to XRF but uses a particle beam to excite the elements in a sample. The detection system is similar to NAA and XRF, and precision, accuracy, and limits of detection are comparable, depending on whether the sample is analyzed in a vacuum or not. PIXE has been used less than NAA and XRF for sourcing CSO because of the limited number of beam lines available on particle accelerators which tend to be in universities and museums (e.g., Accélérateur Grand Louvre d'Analyses Élémentaires (AGLAE)). PIXE can provide a much finer resolution of the sample area analyzed, since the beam line can be focused down to a few micrometers in width. Newer synchrotron accelerators (see SYNCHROTRON-BASED X-RAY ANALYTICAL TECHNIQUES AND MATERIALS ANALYSIS) may provide added possibilities for chemical and physical analyses of rocks and minerals, but to date their application in sourcing CSO has been very limited.

X-ray diffraction

X-ray diffraction (XRD) has traditionally been used in geology to identify the mineral constituents of rocks. As a result, it is a well-established and proven technique. XRD requires a sample to be reduced to a powder, which has limited its application to archaeological artifacts, but, in some cases, artifacts made of stone such as beads can be analyzed nondestructively using a special sample mount and low X-ray incident angles. XRD is not suitable for analyzing obsidian because it requires a crystalline structure.

Inductively coupled plasma

Inductively coupled plasma (ICP) instruments (see ICP-MS AND MATERIAL ANALYSIS) are routinely used in geochemical analyses and are increasingly becoming the standard for archaeological sourcing applications for a variety of materials. In order to deliver the sample to the ICP torch, CSO can be ablated using a laser, or it can be powdered and digested in acids and then analyzed

in solution mode. ICP instruments are then combined with a detector that can quantify either the component chemical elements or specific isotopes (see ISOTOPES). Depending on whether the focus is on specific chemical elements or isotopes, or the complete suite of elements potentially present in a sample, the ICP can be combined with a variety of spectrometers: AAS and OES, or MS (see MASS SPECTROMETRY (MS)). ICP instruments have very low limits of detection, which allows them to measure essentially all of the elements of the periodic table in the parts per billion range or even lower. In addition, the microdestructive aspect makes these instruments particularly attractive for archaeological artifact analysis.

Scanning electron microscope

The scanning electron microscope (SEM) is a versatile imagery instrument that can allow the archaeologist to visualize rocks in different ways (see ELECTRON MICROSCOPY IN CONSERVATION). This gives a better understanding of the mineral make-up of the rock, and how its structure might be characteristic of a CSO. In most cases, SEMs are equipped with an XRF spectrometer which enables the researcher to analyze the chemical make-up of the constituent minerals. SEMs have the advantage of allowing for a higher resolution in the analysis of the rock surface.

Petrography

Petrography is a standard technique for the identification and characterization of CSO. It is destructive, which limits its application to artifacts, but it is an essential step in narrowing the potential geologic universe of a source and correctly identifying a rock. Cherts and silex are relatively easy to differentiate based on fossils and other minerals or structures, which makes this a powerful technique (see also PETROGRAPHY AND CERAMICS).

Linking an artifact found on a site with the source of its raw material

The ultimate goal of sourcing research is to link an artifact found on an archaeological site with the original source of the raw material that was

used to make it, and perhaps to the workshop where this material was transformed. The tens of thousands of CSO artifacts found on archaeological sites around the world attest to the fact that people often traveled great distances to obtain these valuable materials. In other cases, they exchanged goods for these raw materials, or the objects made out of them. The archaeologist can therefore use the data from sourcing studies to reconstruct past territories or trade networks. The primary challenge in reconstructing these past movements remains primarily at the sourcing end. In other words, the quality of the data available for each source of CSO that is known will greatly influence the success that an archaeological scientist has in terms of linking an artifact to its source.

In some cases, the source is simply not known. After more than 50 years of intensive geochemical characterization studies on the obsidians of Mesoamerica, the US Southwest, and the Eastern Mediterranean, researchers in each of these regions still find new sources of obsidian among their artifacts that cannot be linked to a known source based on their chemistry. The case is even more striking in many parts of the world where people used cherts and other widely available siliceous rocks. The sheer magnitude and extent of the geologic formations that house potential sources often makes it impractical to even initiate the sourcing research and this has seriously hampered the development of research in many regions. In terms of silex or flint, the geologic sources of western Europe are largely known and have been studied primarily using micropaleontology. But even in this case, widely separated sources of silex/flint can contain the same fossils, making it difficult to differentiate them and therefore identify the precise source of an artifact. While the instruments and techniques for sourcing continue to improve, their application to sourcing CSO remains constrained by the challenges of sampling the potential geologic universe and the geographic scale of the archaeological research question.

Chromatography and Archaeological Materials Analysis

ALESSANDRA PECCI

Universitat de Barcelona, Spain

Introduction

Chromatography is essential for the study of archaeological organic materials. Since most archaeological organic substances comprise complex mixtures of molecules with a wide range of chemical and physical properties, chromatography's analytical utility is essential to modern archaeological research practice and more broadly to cultural heritage studies. Identifying and characterizing the compositions of archaeological organic mixtures helps archaeologists to interpret ancient people's lifestyles.

Organic materials recovered in archaeological contexts are composed of a mixture of molecules. Chromatography allows us to separate and identify these molecules, being a technique that "allows separating a mixture into its individual components and simultaneously determine quantitatively the amount of each component" (Scott 1995). It allows us to analyze gaseous, liquid, or solid samples, and the analysis can be carried out with expensive instruments or simple techniques.

The word chromatography derives from the Greek words for "color" and "writing." It owes its name to the Russian botanist Mijaíl Tswett, who first employed the technique at the beginning of the twentieth century to separate plant pigments. Chromatography has since developed rapidly and is now used for different separation processes of molecules. In 1952, Martin and Synge, who established the principles of modern chromatography, received a joint Nobel Prize in Chemistry for their contribution to the "invention of partition chromatography."

Chromatographic separation is achieved by distributing the substances to be separated between a moving phase (the so-called *mobile phase* which can be a gas or a liquid) and a *stationary phase* (a solid, or a liquid supported on a solid). In a simplified vision of the technique, the mobile phase flows through the stationary phase and carries the components of the mixture with it, while the stationary phase retains them.

The various constituents of the mixture travel at different speeds—based on differences in characteristics, such as their molecular weight and structure, as well as on their affinities to the stationary and mobile phases—and reach the end of the chromatographic system at different times (it is said that molecules "elute" with different "retention times"). These different speeds of "elution" allow us to separate the mixture into its constituents. The separation processes that use a gas as the mobile phase are called "gas chromatography," while the processes that use a liquid are called "liquid chromatography."

Samples of archaeological materials (e.g., resin, pitch, beeswax, dung, organic residues trapped in ceramic vessels) are usually analyzed as organic solutions and therefore must be extracted by a solvent before their analysis. Depending on the objectives of the analyses and the materials analyzed, different extraction methods can be followed. Chromatographic analysis includes different techniques such as gas chromatography (GC), high-temperature gas chromatography (HTGC), liquid chromatography (LC), and pyrolysis/gas chromatography. Gas chromatography (GC) (see GAS CHROMATOGRAPHY–MASS SPECTROMETRY (GC-MS)) is commonly used, but it is unsuitable for the analysis of high-molecular-weight biopolymers or proteins. Bigger molecules, such as triacylglycerols, can be identified by techniques such as HTGC. In pyrolysis GC, the sample is rapidly heated, and large molecules are fragmented into volatile particles that are later separated by GC. In LC, the mobile phase is a liquid. High-performance liquid chromatography (HPLC) utilizes a high pressure and for this reason is called also high-pressure liquid chromatography.

Chromatography gives better results when it is coupled with mass spectrometry, a highly selective, specific, and sensitive technique that separates ions according to their mass charge (m/z) ratios. Combined, the two techniques allow for the reliable identification and characterization of a mixture of components. GC can be coupled with isotopic analyses in gas chromatography combustion isotope ratio mass spectrometry (GC-C-IRMS) to identify the relative ratio of stable isotopes of carbon, hydrogen, nitrogen, or oxygen in individual compounds and to pinpoint the origin of such substances (Evershed 2008). In combination with accelerator mass spectrometry (AMS), chromatography can make it possible to date the organic residues preserved in the samples (Berstan et al. 2008).

Prior to applying chromatographic techniques, it is important to establish whether or not the samples require any treatment prior to the analysis; which are the most suitable for extraction, derivatization, and analytical methods; and which instruments best suit the analysis of specific materials and best align with the objectives of the research. In archaeological research, good results depend on the application of specific techniques and sampling strategies.

Application

The application of chromatographic techniques to the study of ancient materials has opened new paths in the investigation of different fields, such as the identification of ancient tars, resins, pitches, and incenses, as well as of ancient dyes such as indigo; the understanding of the use and function of ceramic vessels, pipes, and stone tools; the function of rooms and buildings; and the identification of activity areas. These methods have also provided evidence for the early domestication of animals and plants, the introduction of specific foodstuffs in human diets, and the historic consumption of alcoholic beverages and drugs. More broadly, they have yielded information about food practices and diets in different archaeological sites and cultures. Chromatography has also allowed archaeologists to explain ancient production processes and technologies and to ascertain the degradation processes of different substances.

This knowledge has enabled the conservation of ancient materials, and, in some cases, it has been able to identify their forgery.

One of the most important applications of chromatography is the identification of organic residues (amorphous or absorbed by porous materials), which are usually preserved as a mixture of substances (see ORGANIC RESIDUE ANALYSIS). Cooking pots likely contained different foodstuffs. Many substances ended up on kitchen or temple floors while cooking or performing ritual activities. Different oils and animal fats might have been burnt as fuel in ancient lamps. Beeswax and resin might have been mixed to produce a glue; and amphorae containing wine or oil might have been coated with pitch. The possibilities yielded by chromatographic techniques to recognize these various materials have existed since the 1970s, when these were used to investigate amphorae contents and lamp fuels (Condamine et al. 1976).

The difficulty of identifying residues of wine, which, along with oil and fish sauces, was one of the most important commodities traded in the ancient world, has long hindered the study of amphorae contents. However, recent developments in the identification of wine residues with LC and GC coupled to mass spectrometry have given new impetus to this line of research. They have made it possible to study wine's origins, its production and consumption at different sites, and its use as an offering for the dead and for gods. The consumption of other beverages, such as pulque, chicha, and black drink (a pre-Columbian North American beverage), as well as chocolate and beer has also been established thanks to the identification of specific biomarkers through chromatographic techniques.

Lipids are among the compounds more commonly identified in organic residue analyses (Evershed 2008). By studying their distribution and isotopic signature, it is possible to establish the various species of animals consumed in different areas of the world, to distinguish between adipose fats and dairy products, and to identify evidence of ancient dairy product consumption. Proteins can also be identified with chromatographic techniques—albeit with due care in interpretation—and their study gives clues regarding many interesting aspects of

ancient daily life. Proteins are often well preserved in dental calculus, and their recognition facilitates a deeper understanding of food consumption in different regions and periods.

In recent decades, organic residues analysis carried out by chromatographic techniques has concentrated mainly on the analysis of ceramic materials. However, the technique can be used to identify residues preserved in other porous materials, such as the plaster used to make floors in different areas of the world or to make the coatings of vats from production installations for wine, oil, or fish by-products. The analysis of such materials has often been carried out by means of spot tests, and the combination of spot tests with GC has helped to interpret data and to produce knowledge about the function of rooms, buildings, production structures, and spaces in general (Pecci 2013; Pecci, Cau, and Garnier 2013).

Chromatographic techniques have also been applied in the analysis of beaten earth floors, fireplaces, anthropogenic soils, and ancient cultivation fields, as well as in the identification of dung traces in the archaeological record. They likewise play a crucial role in the characterization of amorphous materials such as beeswax, resin, pitch, incenses, tars, bitumen, and gums. These are found as bulk materials transported and preserved in ancient vessels, such as incense burnt during rituals, as waterproof linings of vessels, boats, or buildings; as glues used to repair ceramics or to make other artifacts such as knives, projectile points, masks, and many other ritual and domestic tools; and as glues for body and teeth decoration. Such substances can also be identified in the pores of ceramic matrices, since they were used as waterproofing agents in ceramic vessels and as preservatives and flavorings. Chromatographic analysis sheds light on the use of these materials, their production processes, and their geographic origins (Stern et al. 2008).

Chromatography has found many more applications. It has been used to characterize fossil resins such as amber and to identify the polymers used to imitate these materials and others (such as precious stones). It can characterize waterlogged archaeological wood, making it possible to determine degradation processes and to develop consolidation and conservation procedures

(Colombini et al. 2007). Finally, the application of chromatographic analyses to cultural heritage can identify the original techniques used to paint and glue and the substances used in previous conservation processes.

Future directions

Chemical analyses in archaeological research should always be conducted in collaboration with a team comprising historians, archaeologists, chemists, archaeozoologists, and materials specialists such as botanists in order to accurately understand the materials investigated (and the degradation processes that they have undergone) and to contextualize the results obtained. The interpretation of chemical results must take into account the archaeological contexts where materials were recovered and answer the historical and archaeological questions that prompted the analyses. Likewise, ethnoarchaeology and experimental archaeology should be integrated in the study to better identify the archaeological substances investigated, their use, and their production processes.

Clay Tablets

YUVAL GOREN

Ben-Gurion University of the Negev, Israel

Cuneiform is a system of writing first developed by the ancient Sumerians in Mesopotamia during the fourth millennium BCE. The name comes from the Latin word *cuneus* for “wedge” owing to the wedge-shaped style of writing. The canvas for writing in cuneiform script was soft clay, onto which a stylus was pressed to form wedge-like word-signs. It is estimated that between half a million and two million cuneiform tablets have been found in modern times, of which only less than 100,000 have been read. Hence, cuneiform tablets form immense collections of hundreds of thousands of documents, representing the dynamics of cultural interactions and literary processes of the Ancient Near East (ANE) during the third, second, and first millennia BCE. This period constitutes the heyday of the great empires from the Early to the Late Bronze Age, which gave birth to the compilation of the great corpora of the ancient world. This period witnessed the production and dissemination of a large quantity and variety of textual materials written upon clay tablets by means of the cuneiform script in several languages (Akkadian, Sumerian, Hittite, Hurrian, and Northwest/West Semitic dialects). These textual materials dealt with matters of state, administration, law, religious life, literature, economy, magic, medicine, and the art of divination.

For nearly a century, the study of clay tablets was restricted only to Assyriologists, who devoted their studies to historical, linguistic, paleographic, and epigraphic aspects of the script. Only in the 1970s it was noted that clay tablets may be approached from an entirely different angle, through scientific analysis of their clay. By applying the protocols used for chemical and mineralogical composition of ceramics (see *CHARACTERIZATION OF CERAMICS*), the problem of locating the provenance of ANE clay cuneiform

tablets can be addressed. Such studies, employing neutron activation analysis (NAA) (see *NEUTRON ACTIVATION ANALYSIS (NAA)*), were first made to tackle the identification of specific toponyms (Artzy, Perlman, and Asaro 1976). However, despite some informative results, this approach was discontinued. Only towards the turn of the twenty-first century and with this notion in mind, several comprehensive studies have been conducted (Goren, Finkelstein, and Na'aman 2004). Through petrographic (see *PETROGRAPHY AND CERAMICS*), inductively coupled plasma mass spectrometry (ICP-MS) (see *ICP-MS AND MATERIAL ANALYSIS*), and NAA studies of samples from documents from the Amarna archive, Ras Shamra-Ugarit, Boğazköy-Hattuša, Babylon, several cities in Palestine and Israel, and Cyprus, these studies aimed at pinpointing the technology and geographic origin of tablets, thus clarifying the geographical history of the ANE. The theoretical basis for such studies lies in the fact that archives of cuneiform texts contain numerous tablets whose origin is unknown. Letters often contain the name of the sender, but sometimes the letterhead is partly or entirely missing; in other cases, we may have the name of the sender and still ignore his domicile. Worst of all, the location of some ANE countries and towns has not yet been clearly established. Moreover, documents other than letters might be assigned to an origin only by their style or location of discovery, but this may remain a matter of dispute. In such cases, scholars can only hope to find some paleographical, linguistic, or thematic clues for the origin of a document.

This methodology enabled for the first time scientifically based provenance study of hundreds of clay cuneiform tablets, using mineralogical and elemental methods. While the former identified the minerals in the clay and temper of the tablet, the latter used diverse analytical techniques to measure the concentrations of the elements in the clay. These studies have demonstrated firstly that cuneiform tablets were not always produced of the same clay types as the local pottery; hence they should be treated separately from other archaeological ceramics. Second, while

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0095

pottery can be usually studied by the routine mineralogical and elemental methods involving intrusive sampling, clay tablets are unique and delicate and the sampling, if allowed at all, should be much below the standards of the regular petrographic and elemental examination procedures. Therefore, the main effort must be directed to the development of new methodologies, with the support of nondestructive techniques (see NONDESTRUCTIVE COMPOSITIONAL ANALYSIS OF CERAMICS). As Goren, Mommsen, and Klinger (2011) have shown, these are suited for the analysis of large numbers of clay tablets in museums and collections using portable apparatus such as portable X-ray fluorescence (pXRF), Raman spectroscopy (see RAMAN SPECTROSCOPY AND MATERIAL ANALYSIS), and surface Fourier transform infrared spectroscopy (FTIR) (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)). If a museum having collections of tablets is equipped with an environmental scanning electron microscope with attached electron dispersive X-ray spectroscopy (ESEM-EDS), formation processes of the tablets can be made without extracting samples (Cartwright and Tylor 2011). The results of these nonintrusive methods can be manipulated on location and compared with an existing database of clay compositions of cuneiform tablets. This can serve to select samples for further mineralogical (petrographic) study,

to be extracted by minimal sampling techniques (Goren et al. 2004, 4–12) and processed if needed on location using a portable petrographic laboratory. In turn, the leftovers from their preparation process can be used for a further set of analytical techniques for the determination of clay mineralogy by X-ray diffraction (XRD) (see XRD AND MATERIALS ANALYSIS), the determination of firing temperatures by thermogravimetric analysis, and absolute dating by archaeomagnetic intensity (see ARCHAEOMAGNETIC DATING OF BAKED CLAY FEATURES).

Dyes

TATIANA FALCÓN

Universidad Nacional Autónoma de México, Mexico

Dyes or colorants are organic substances dissolved in solution when applied to a substrate. The attachment of the dye to the substrate is achieved through chemical interactions or physical entrapment processes. Dyes are regularly used to color fibers (see FIBERS), so they are expected to be found on textiles (see TEXTILES); but they have also been used to color leather, furs, feathers, wood, paper, and parchment. In the past, dyestuffs were extracted from a great variety of sources: flowers, leaves, barks, fruits, roots, lichens, mushrooms, insects, and molluscs.

In traditional textile dyeing, colorants are divided into three groups, according to the dyeing procedure: direct dyes are applied to the fiber substrate directly; vat dyes need to go through a chemical reduction process that transforms the colorant into a soluble precursor before dyeing; and mordant dyes are fixed to the fibers with the aid of metal ions called mordants, which act as bridges between the dye and the fibers, creating chemical bonds. Dyes may become pigments (see CHARACTERIZATION OF PIGMENTS) by being precipitated onto an insoluble inert substrate such as clay, hydrated alumina, or chalk; and then they are called lake pigments. Pigments, on the other hand, are organic or inorganic insoluble, finely grinded, and colored particles that need a binder in order to be fixed onto the substrate's surface.

Dyes may also be classified by their chemical structure. The main chemical groups found in nature are quinones, flavonoids, carotenoids, indigos, and tannins. Anthraquinoid dyes are the most important subgroup of the quinones. Their sources vary in nature: they are present in the roots of different madder species (*Rubia* spp.) or in the bodies of scale insects such as Mexican, Polish, or Armenian cochineal (*Dactylopius coccus*, *Porphyrophora polonica*, and *Porphyrophora hamelii*, respectively), lac (*Kerria lacca*),

and kermes (*Kermes vermilio*). Flavonoids are responsible for most yellow dyes, but may yield a wide array of different hues. Reds from the heartwoods of sapan and brazilwoods (*Caesalpinia sapan*, *Caesalpinia brasiliensis*, *Haematoxylon brasiletto*) belong to a subgroup of the family called homoisoflavonoids. Less firm yellows, such as carotenoids and curcumins, are also used for dyeing and painting. For example, the orangey-red of annatto or achiote (*Bixa orellana*) is used by Amazonian people to decorate their bodies, and the Mayans of Yucatan use it to color food. Indigoids yield very stable, even permanent blues and purples. The first are extracted from different plant sources around the world; the second come from sea snails and were exploited by different ancient groups along the Mediterranean and Pacific coasts of North and South America.

Dye sources that produce stable, lightfast colors are few. Before William Henry Perkin's discovery of the first aniline in 1856, good-quality dyestuffs were in high demand; they were considered luxury goods and many of them had to be imported from faraway lands. Since the beginning of the Middle Ages, Europe's most important manufacturing centers bought silk fibers and textiles along with indigo, redwoods, and insect dyes from the Far East and India through the Silk Route—a network of trade routes that connected Europe with the Far East via Asia Minor; it existed since around the third century BC and continued until 1453, when the Ottomans in Constantinople blocked relations with the West. Commercial routes promoted connections between people, and therefore the coexistence and merging of cultures in terms of art, religion, politics, language, philosophy, science, and technology, as well in terms of the trade of material goods.

The conquest of the New World gave the Spanish and the Portuguese crowns the opportunity to introduce a whole new group of dyeing sources into the Eurasian markets. Mexican cochineal (*Dactylopius coccus* Costa), along with various species of dyewoods (redwood, *Haematoxylon brasiletto*; logwood, *Haematoxylon campechianum*; old fustic, *Maclura tinctoria*; brazilwood,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0203

Caesalpinia brasiliensis) and indigo-producing plants (mainly *Indigofera suffruticosa*), began to be exploited and merchandized soon after the conquest and Spain's subsequent expansion into Aztec territory. Due to its great color yield, the Mexican cochineal became Spain's second most priced good after silver.

The characterization of the materials out of which the objects of our world heritage are constituted begins to unfold, as multitechnique strategies and methodologies are brought together for their study. Our understanding of the differential use of colorants and pigments—that is, of the procedures and technologies used in their manufacture and application as dyes (e.g., on fabrics) or as paints (e.g., on canvas) has developed profoundly thanks to a combination of scientific and humanistic skills: archaeometry (see *ARCHAEOLOGY*), archaeology (see *ARCHAEOLOGIES OF TECHNOLOGY*), art history, biology, conservation science (see *CONSERVATION SCIENCE*), chemistry, ethnography (see *ETHNOGRAPHY AND QUALITATIVE METHODS IN THE FIELD*), physics, and technical art history are some of the professions that join in collaborative projects dedicated to the study of the past. The combination of archival investigation, experimental reconstructions, fieldwork, and scientific analyses of both reconstructed and original samples has become a regular procedure.

The material evidence that survives from the past consists largely of examples of unique and precious objects that were used on special occasions and with particular intentions: representations of deities or ancestors, votive offerings, the attire of religious and political authorities, military uniforms, clothes of wealthy men and women, and so on. For this reason they were safeguarded with the utmost care, both during their serving lives and after. Analytical studies of both textiles and works of art from the past confirm the use of precious materials for their confection. We may assume that local coloring sources were also amply employed, but the lack of written documentation and precludes the possibility of using reference materials in our analyses, which makes the identification of these sources quite difficult.

The clash of cultures in subjugated territories led the victors to the discovery and exploitation of materials until then unknown to them. The incorporation of new supplies often prompted

the craftsmen to adapt new methods and working techniques. The observations recorded by Francisco Hernández (c. 1515–87) in his *Historia natural de Nueva España* (*Natural History of New Spain*) and by Bernardino de Sahagún (1499–1590) in his *Historia general de las cosas de Nueva España* (*General History of the Things of New Spain*) on how the Nahua people used dyestuffs for dyeing and painting are a good example. Hernández was commissioned by Philip II of Spain to document the natural richness of the newfound kingdom. He had to pay special attention to the cataloguing of plants with medical properties and to record the illnesses they were used for, how they were prepared, the form in which they had to be applied or taken, and the efficiency of their use. Many of the dyestuffs he recorded had medicinal properties; but Hernández also noticed the impact that the exploitation of such materials could have on the crown, given the economical significance of the European textile industry. Sahagún explains that his interest in recording things related to the natural realm is mainly philological. As a mendicant friar, his primary concern was to understand the indigenous way of thought in order to guarantee the conversion of the pagans. He was convinced that language was the most reliable tool for true communication among people and for their understanding of one another. His chapter on color (chapter 11 in Book 11 of his *General History*) incorporates recipes for the preparation of lake pigments and dyes. It is evident that his closeness to the indigenous scribes who helped him carry out his investigation and illustrate his manuscripts made him more appreciative of the importance and possibilities of lake pigment manufacture.

For many reasons, the information regarding the sources and preparation techniques of dyes and pigments is invaluable for archaeologists, art historians, ethnographers, and conservators who try to decipher the body of material culture (see *MATERIAL CULTURE*). They need to establish the provenance of objects, to determine attributions to specific cultural groups, to date various materials, to understand technologies of fabrication, commercial transactions between nations, and power relations, and to confer meaning to all this complex (see *HERITAGE INTERPRETATION*). The chemical identification of the materials used to

make up an object may also explain its deterioration, give clues as to its original appearance, and help establish the best conservation strategies and treatments for it. Recipe books, artists' treatises, pharmacological books, travellers' notes are just some of the primary sources that investigators study in their search for information that may prove useful in understanding the material choices made by an artist. Likewise, modern and contemporary ethnography has studied and recorded the techniques of textile art and painting, which on many occasions can be linked to historical documents or to objects.

The identification of the chemical structures of dyes is complex. The high tinting power of dyes implies that they are found in small quantities and, owing to the dyeing and pigment fabrication methodologies, are usually mixed in complex matrices, either attached to a fiber with the aid of a mordant or combined with binders and other pigments when used for painting. High-performance liquid chromatography (see HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC)) is still the best alternative for colorant characterization because it separates the different compounds within a sample and identifies them separately. The downside to chromatographic technologies is the need to extract samples from the object to be analyzed (see CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS). These methods also require the use of reference standards for the proper identification of the compounds. The responsiveness of the new equipments—known as ultra high-performance liquid chromatographers (UHPLC) on account of their enhanced sensitivity—allows the positive detection of fractions of a microgram. As a consequence of the technological developments, sampling has become less damaging than it used to be in previous decades. Chromatographic analyses have also been performed with the aid of photo diode detectors that register the characteristic radiation absorption of colorants at specific wavelengths. HPLCs may be coupled to a mass spectrometer (see MASS SPECTROMETRY (MS)) for the determination of molecular weight that leads to the designation of molecular structures.

Vibrational techniques, such as Raman spectroscopy (see RAMAN SPECTROSCOPY AND MATERIAL ANALYSIS) and Fourier-transformed infrared spectroscopy (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), have also developed new systems that improve the detection limits of the equipment. Surface-enhanced Raman spectroscopy (SERS) or micro-FTIR are being used more often, giving very positive results in the identification of dyes. Nondestructive and microanalytical techniques can be worked directly over the object without sampling. In the past decade, experimentation with reflectance spectroscopy in the visible and near infrared region has proved to be a useful tool that gives the field good preliminary information at a good speed.

Artifacts are usually integrated into complex mixtures, through superpositions or layers of materials. Their study requires implementation of different analytical techniques and laborious sample preparation. The analytical strategies should be tailored to a clear objective and done by professionals in each of the specialties involved.

Elemental Analysis of Pottery

ANNO HEIN

National Centre for Scientific Research (NCSR)
"Demokritos," Greece

History

In comparison to other archaeological materials such as pigments (see CHARACTERIZATION OF PIGMENTS), metals, and glass, the first chemical analyses of archaeological pottery were implemented relatively late—at the end of the nineteenth century (Riederer 1981) (see CHEMISTRY IN ARCHAEOLOGY). The initial scope of the early analyses was the understanding of specific production technologies, such as terra sigillata. During these years, wet chemistry was the only choice of analytical approach for determining the chemical composition, requiring elaborate procedures for the disintegration of the silicates and determination of their components. Nevertheless, first conclusions towards the potential of distinguishing pottery from different production regions based on their elemental composition were drawn, shifting the scope towards provenance. Systematic scientific studies of archaeological ceramics in view of their origin, however, became possible only with the technical development of instrumental analytical methods towards the beginning of the second half of the twentieth century. A series of pioneering studies were implemented, using various methods such as neutron activation analysis (see INAA AND MATERIAL ANALYSIS) (NAA), X-ray fluorescence (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)) (XRF), and optical emission spectroscopy (OES), which eventually can be considered as the starting point of systematic investigation of the elemental composition of archaeological ceramics (Wilson 1978). Since then, elemental analyses of pottery have been subject to substantial developments in analytical techniques and advancements in scientific approaches. While, in the beginning,

the focus of pottery studies was on assessing the principles of elemental analysis and testing the potentials, in the following phase, more and more data were collected, compared, and interpreted in view of specific archaeological questions.

The archaeological scope of elemental pottery analysis remained twofold: to investigate production technology and technology transfer, on the one hand, and dissemination of pottery, on the other. Because occasionally it appeared that elemental analysis by itself could not answer all questions, it was combined in interdisciplinary case studies with alternative methods of pottery examination, such as thin-section petrography (see PETROGRAPHY AND CERAMICS), mineralogical examination, or scanning electron microscopy (SEM). Based on these case studies, an integrated approach to pottery examination developed which essentially improved the data interpretation (Day et al. 1999). Nowadays, elemental analysis of the bulk composition and of surface layers is an integral part of the vast majority of pottery studies, accumulating large amounts of reference data. A relevant technical development during recent years is the feasible application of noninvasive analytical methods such as portable XRF (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)) (pXRF) in cases in which sampling is not possible (Goren, Mommsen, and Klinger 2011). Nevertheless, the laboratory analysis of pottery samples appears to remain important in order to achieve a comprehensive picture of their elemental composition and to build up reference databases.

Bulk composition of pottery

The elemental bulk composition of a ceramic body depends primarily on the elemental compositions of the raw materials that were used for its fabrication. These are basically different types of aluminosilicates containing various accessory minerals. The assumption that raw material sources can be chemically distinguished is the basis for the approach of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0211

investigating the provenance of pottery based on its elemental composition. The distinctness of raw material sources was formulated in the so-called provenience postulate presuming that “there exist differences in chemical composition between different natural sources that exceed, in some recognizable way, the differences observed within a given source” (Weigand, Harbottle, and Sayre 1977).

It has to be considered, though, that pottery itself is not a raw material. For pottery production, a workable clay paste had to be prepared in order to mold an object, with the additional constraint that this object could withstand the subsequent firing without damage. This required usually some modification of the collected raw materials, such as refinement by grinding, sieving, and elutriation, in order to remove coarse nonplastic components from the clay. It was also quite common to mix different raw materials or to add nonplastic materials as temper in order to control the material properties of the molded object and, more important, of the final product. Therefore, the elemental composition of pottery commonly cannot be linked directly to raw material sources.

The firing of the pottery affected the elemental composition through loss of ignition mainly due to dehydroxylation of the clay paste. With increasing temperature, first the mechanically bound water between clay particles and/or mineral inclusions was removed and later the crystal-bound water, which made the firing process eventually irreversible. Other processes during the firing affecting the bulk composition of the clay are, for example, the loss of molecular carbon dioxide in calcite inclusions and the combustion of organic components. All these processes, however, increased only the absolute concentrations of all other elements, while the ratios of their concentrations remained basically unaffected during firing. Considering the common firing temperatures of archaeological pottery, only a very few elements, such as arsenic and bromine, could be potentially affected by loss due to volatilization.

Consequently, it can be assumed that the *chaîne opératoire* of a specific pottery production, including steps such as raw material selection, clay paste preparation, and the firing process, resulted in a distinct elemental composition

of the final product. This distinct composition is often called the “chemical fingerprint” of a pottery workshop. After all, provenance studies of pottery are indeed based on the provenience postulate including all constraints, such as inner source variability and the nonexistent evidence for its validity.

The elemental composition of the archaeological artifact measured in the laboratory, at last, is not necessarily the same as the original elemental composition of the object. Significant chemical alterations due to use and function of common pottery can be largely excluded, maybe with the exception of technical ceramics used, for example, in pyrotechnical processes. After use, though, the pottery may have been potentially affected by post-depositional alterations. Between use and discarding of the pottery and its discovery, the material was usually exposed to various environmental influences, causing alterations of specific element concentrations by contamination, enrichment, or leaching. Basic examples are rehydroxylation of the fired clay and the formation of secondary calcite enhancing the calcium content. More complex alteration processes can have occurred in extreme environments, such as marine and agricultural contexts. Therefore, the finding context has also to be considered in the integrated elemental analysis of pottery.

Surface composition of pottery

Specific attention should be paid to the elemental composition of the pottery surface. Depending on the surface finishing, the surface composition can be quite different from the bulk composition. Even rather basic techniques such as burnishing and polishing can have had an effect because through the smoothening, commonly by using additional water, the clay paste was refined, reducing nonplastic components such as quartz and carbonates.

In the case that a separate slip was applied, an aqueous slurry had to be prepared. One way to prepare this slurry was the elaborate refining of the clay paste used for the construction of the ceramic body by elutriation. In this way, larger particles were effectively removed, resulting in a proportional enrichment of the clay fraction. In

order to further enhance the vitrification of the slurry during firing, it was sometimes mixed with materials acting as flux, such as potash extracted from plant ash or ash from seaweeds.

Alternatively, the slurry for the slip could have been prepared from different raw materials particularly suitable for slip preparation rather than for body construction. A well-known example is the use of illitic iron-rich clays for the production of Attic black ceramics (Noll, Holm, and Born 1985). But also other types of clay were selected and prepared for slip or paint layers, achieving different colors. These layers, however, did not interact with the actual ceramic body and thus had no effect on the bulk composition of the pottery. This is different in the case of vitreous glazes. Their elemental composition was fundamentally different from the ceramic body and they were additionally mixed with colorants and opacifiers, which potentially could penetrate and contaminate the ceramic body (see GLAZES, SLIPS, AND PAINTS).

Choice of method

In the case of the investigation of archaeological materials, impairment of the studied objects should commonly be restricted to the absolute minimum. Ideally, the analysis should be non-invasive in order to ensure the integrity of the object (see NONDESTRUCTIVE COMPOSITIONAL ANALYSIS OF CERAMICS). In the case of pottery, however, it has to be considered, as already mentioned above, that the elemental composition of the surface is commonly different from the bulk composition. Additionally, in the case of post-depositional alterations and incrustations, these will concern primarily the pottery surface. Therefore, even when using a noninvasive analytical method like pXRF, at least the surface of the pottery should be removed in order to investigate its bulk composition.

Indeed, most analytical methods, used routinely for pottery analysis, implicate sampling of the pottery. In the case of pottery fragments or shards, this is usually acceptable and the samples can be used also for other methods in view of integrated examination. The necessary sample amounts vary from several milligrams, as in the case of inductively coupled plasma spectrometry

mass spectrometry (see ICP-MS AND MATERIAL ANALYSIS) (ICP-MS), up to several grams, as in the case of wavelength-dispersive X-ray fluorescence (WDXRF), optical emission spectroscopy (OES), and atomic absorption spectroscopy (AAS). Even though the sample amount should be kept at a minimum, it should be large enough to represent sufficiently the material. The suitable amount depends essentially on the type of pottery in view of its homogeneity and coarseness. Commonly, pottery samples are taken by clipping and subsequent powdering or by drilling. Alternatively, small samples can be taken and immediately analyzed by laser ablation, as in the case of laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) and laser-induced breakdown spectroscopy (see LASER-INDUCED BREAKDOWN SPECTROSCOPY (LIBS)) (LIBS). For other analytical methods, a more or less elaborate sample preparation is necessary, potentially involving silicate dissolution or fusion of the sample powders. Sufficient avoidance of contamination during sampling and sample preparation is self-evident.

Among the various methods that can be used for elemental analysis of pottery there exist substantial differences in terms of the elements, the concentrations of which are feasible to determine, and in terms of detection limits and precision. Each method provides actually only a limited selection of element concentrations. Some methods, such as XRF, OES, and AAS, are rather suited to analyzing major and minor elements, while others, such as NAA and ICP-MS, are adapted to trace element analysis. The choice of a suitable method depends on the questions to be solved in the analytical study. In the case of provenance studies, for example, a sufficient number of trace element concentrations measured with high precision is necessary to distinguish pottery produced from different clay pastes, while major element compositions provide rather more information about clay paste preparation and preferences for specific types of raw materials.

Another issue to be considered in the choice of a suitable analytical method is the potential for comparing new data with existing reference data. Even though comparison of element concentrations determined with different methods is basically possible, practical experience has indicated that comparison of data determined with the

same or a similar method is more straightforward. It should be taken into account that apart from the precision, which is the reproducibility of the applied method, also the accuracy, which is the closeness to the true value, is relevant for comparing individual element concentrations. Therefore, it may be necessary to estimate calibration factors for interlaboratory comparisons.

In certain case studies, the spatial distribution of the elemental composition can be the object of investigation, for example when slip or paint layers are explored. In this case, the analysis can be combined with microscopic examination. A common approach is SEM of pottery sections in combination with energy-dispersive spectroscopy (SEM-EDS) or electron microprobe (EMP). Alternatively, laser ablation can be used for ICP-MS or X-ray spectroscopy at microscale, using μ XRF (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)) or particle-induced X-ray emission (see ION BEAM ANALYSIS (PIXE/RBS)) (PIXE).

Variation of the elemental composition

Most of the interpretation of the analytical results is based on the evaluation of similarity or dissimilarity of elemental compositions. Similar bulk compositions are expected to indicate common origin of production, while dissimilar bulk compositions indicate different origin. Looking, on the other hand, at the surface layers, specific differences of the surface composition compared with the bulk composition indicate particular surface treatments. The reference pattern of a pottery production site, however, is actually not a “chemical fingerprint,” which would refer to a singular elemental composition. In fact, the determined elemental composition always implicates variation. The starting point was the natural geochemical variation within the selected raw material sources, which is already described in the “provenience postulate.” The clay paste processing introduced further variation, because the craftspeople were interested in the preparation of a workable clay paste rather than complying with specific recipes and exact amounts of components. The elemental composition, measured with the analytical method of choice, eventually introduces analytical uncertainties, additionally

interfering with the compositional variation of the pottery.

Therefore, in the case where an elemental reference pattern of a specific production site is investigated, it appears commonly to be necessary to analyze multiple pottery samples from the site in order to define the average element concentrations and to estimate their variation. Elemental analysis should always start with a well-considered sampling strategy. The similarity or dissimilarity of two element compositions can only be assessed under consideration of their variations. The compositional variation finally affects the level up to which pottery production of different origin can be distinguished. If the natural variation of the raw materials commonly used for pottery production was small throughout a specific region and extensive clay paste processing was not necessary, it can be difficult to distinguish different production sites within the region. In other cases, it can be possible to distinguish even individual pottery workshops at the same production site. In any case, the analytical method has to be suitably selected in order not to obscure potential compositional differences by introducing unnecessarily large analytical variation.

Statistical treatment of elemental compositions

In order to explore similarity or dissimilarity of elemental compositions, the analytical data have to be evaluated using suitable statistical approaches. Certain constraints have to be considered due to the nature of pottery compositions. The variation of a specific element concentration within a series of pottery samples, for example, can be estimated by determining the standard deviation of the measured values, presuming, though, a normal distribution of concentration values. In the case of the natural variation of trace elements, however, their concentrations are expected to follow rather a log-normal distribution. Furthermore, element concentrations in pottery are not completely independent of each other. Particular elements are correlated because they are associated with the same mineral components, which can vary in the original clay

paste or be affected by post-depositional alteration. Finally, a general enrichment or depletion of trace elements can be related to the addition of varying amounts of temper materials, which are poor in trace elements, or to variation of the firing conditions and the correlated loss of ignition.

The assumed natural log-normal distribution of element concentrations can be accounted for by using logarithmically transformed data. This has the additional advantage of a basic normalization of the data, which appears to be necessary because the absolute concentrations of the individual elements range over levels from sub-parts per million (ppm) to weight percent. In order to consider correlations, ratios of element concentrations can be evaluated instead of absolute concentrations. In the variation matrix, defined by Aitchison (1986), logarithmized ratios of all element concentrations are evaluated, providing the “total variation” as a measure for the compositional variation of the studied assemblage. Log-ratio transformed data can be used for further exploration of the dataset with multivariate statistical methods such as hierarchical cluster analysis (see CLUSTER ANALYSIS) or principal component analysis (see PRINCIPAL COMPONENT ANALYSIS) (PCA).

An alternative approach for considering element correlations is the use of the Mahalanobis distance for determining probabilities of the similarity or dissimilarity of compositional groups (Bieber et al. 1976). This distance is based on the covariance matrix of the element concentrations of a group of samples, which are presenting assumedly the same elemental composition. The data are normalized by their variations. Individual samples can be compared with a compositional group and in the case of similarity they can be incorporated. In order to adjust the above-discussed general enrichment or depletion of trace elements, an additional best relative fit can be introduced.

Embalming

PATRICK EPPENBERGER and FRANK RÜHLI
University of Zurich, Switzerland

Throughout history, practices to preserve the human body after death, and thus to stabilize it against degradation by impeding enzymatic and microbotic activity, and sometimes also to restore its antemortem appearance, are a cross-cultural phenomenon (Lynnerup 2007; Papageorgopoulou et al. 2009). Religious beliefs, especially those that link the achievement of eternal life to the intactness of the body, are the earliest motive for which corpses were artificially embalmed. These beliefs were surely supported by the observation that bodies did not decompose under certain conditions in which partial or complete natural preservation occurred, such as freezing, desiccation by dry heat, exsiccation by dry cold, or under specific soil conditions. Only much later, the rising interest in human anatomy led to the development of techniques for the preparation and preservation of anatomical specimens and, consequently, to a progressing separation of embalming practices carried out in a funerary context and those performed for scientific or diagnostic purposes (Brenner 2014). Generally, the history of embalming is divided into three main periods: (1) ancient societies including those of ancient Egypt and Nubia, the Guanches, South America (the Chinchorro people being the earliest who performed artificial mummifications), and Asia; (2) medieval Europe and the Renaissance, often known as the “anatomist’s period of embalming,” characterized by an increasing demand for cadaver studies as a consequence of scientific developments, particularly in medicine; and (3) the modern era, starting in the nineteenth century with development of reliable methods to inject various chemical preservation agents, nowadays mainly formaldehyde, into the arterial system (Brenner 2014).

With the advance of tissue fixation and histopathological examination techniques for diagnostic objectives, paleopathological investigation of ancient embalmed specimens has evolved further. Besides invasive examination methods, such as histological analysis, analysis by gas chromatography and mass spectrometry, and ancient DNA analysis, noninvasive examination by various imaging techniques based on computed tomography (CT), magnetic resonance imaging (MRI), and recently terahertz (THz) imaging has been applied in several interdisciplinary research projects (Ruhli, Chhem, and Boni 2004; Lynnerup 2007; Papageorgopoulou et al. 2009; Giuffra et al. 2011).

Ancient societies

The Chinchorro populations were sedentary hunter-gatherers who inhabited the arid Pacific coastal regions of the Atacama Desert in present-day Chile and Peru from approximately 7000 to 1500 BCE. They belong to the earliest societies that performed artificial mummification. The oldest artificial mummy, a children’s mummy from the Valle de Camarones, could be dated to about 5000 BCE. In the following 3,500 years, various styles of mummification evolved, until the practice of mummification among the Chinchorro came to a halt around 1500 BCE. The Chinchorro mummies vary greatly in the degree of complexity and sophistication of the applied mummification techniques, which can be differentiated into black mummies, red mummies, mummies with bandages, mummies with mud patina, and naturally mummified bodies.

The different artificial mummification practices involved various intentional alterations of the cadaver, such as skinning, defleshing, evisceration, and excerebration, followed by often elaborate layered remodeling using organic and inorganic materials, depending on the extent to which the body was initially dismantled. The natural mummification process, on the other hand, essentially consisted of letting the corpse

desiccate in the salinity and dryness of the Atacama Desert. The varying practices most likely correspond to cultural changes over time rather than social hierarchy or different coexisting cultural groups. However, since the Chinchorro populations buried their dead with very few cultural offerings, a certain type of mummification cannot be correlated to a specific material culture. Findings also indicate that many of the recovered mummies, especially black- and red-style mummies, have at the time been repaired, possibly because they were used in the context of religious rituals before eventually being buried in family groups (Arriaza and Standen 2002).

The mummies of ancient Egypt are probably the supreme exemplification of procedures applied against the natural process of putrefaction and therefore disfiguration and eventual loss of the dead body. As early as the First Dynasty (approximately 3150–2890 BCE), specialized members of the priest caste were responsible for embalming and mummification. While the motives for artificial embalming traditions were of religious nature, the actual embalming techniques are likely to have originated from an imitation of the natural dehydration process of ancient burials in the desert. As the proto-archaeologist Anne-Claude-Philippe, Count of Caylus (1692–1765), stated in 1749: “It appears that the Egyptians owe the idea of their mummies to the bodies they discovered dried in the burning sands of a region in Egypt, which, carried away by the winds, bury travelers and preserve their bodies, consuming fats and flesh, without altering the skin” (Gannal 1841).

Over the centuries, the embalmers of ancient Egypt introduced three fundamental steps for their sophisticated mummification procedures: evisceration (and excerebration) of the body, desiccation in natron, and anointment with natural compounds, with polymerization of unsaturated oils and fats contained in these anointments being the main principle of tissue fixation. Their exact composition, however, remains uncertain, due to the absence of primary textual evidence. Based on the only available secondary literature by Herodotus (484–430 BCE), Diodorus Siculus (first half of the first century BCE), Strabo (approximately 63 BCE–23 CE), and Pliny the Elder (23–79 CE), the use of beeswax, plant oils and plant resins, animal fats, various aromatics,

and even petroleum bitumen can be presumed. A few published studies have confirmed some of these assumptions by gas chromatography and mass spectrometry, with results greatly varying over different time periods and locations (Buckley, Clark, and Evershed 2004; Papageorgopoulou et al. 2009).

The Guanches on the Canary Islands also practiced mummification techniques based on evisceration and drying of the corpse. The majority of these mummies were produced prior to Spanish colonization of the Canaries during the fifteenth century. Here the cadaver was eviscerated through an abdominal or lateral incision, washed with salt-water, and eventually filled with resins and aromatic oils. Another less expensive method was to inject a highly corrosive liquid into the abdomen, so that the dissolved and liquefied viscera could be swept out. The bodies treated in this fashion were then dried in the sun or smoked for 50 days. Finally the bodies were coated with ointments and resins, then wrapped in goatskins, and eventually placed in tree trunks or deposited in funeral caves.

Another ancient preservation method was the immersion in honey. Publius Papinius Statius (40–96 CE) reports on the Greek emperor Alexander the Great (356–323 BCE) being subjected to such treatment after his death, so that his remains could be transported from Babylon to Alexandria. However, it is unknown whether Herophilus of Chalcedon (approximately 330–255 BCE) and Erasistratus of Ceos (approximately 304–250 BCE), who only a few decades later conducted anatomical studies in Alexandria, also used this method (Longrigg 1988; Brenner 2014).

In China, extraordinarily well-preserved artificially embalmed human remains have been found in the tombs of Xin Zhui and Mawangdui Han, which date back to the Han dynasty (206 BCE–220 CE). However, little is known of the embalming agents and procedures that were applied (Bonn-Muller 2009).

The knowledge and practice of artificial embalming had spread to Europe from the ancient societies by about 500 CE, with evisceration therefore still characterizing the principal measure to prevent the cadavers’ decay (Giuffra et al. 2011). Only a few earlier cases have been reported from the time of the Roman Empire, such as a partly mummified body, found in

northern Greece, which was dated to 300 CE. A chemical analysis identified compounds of coniferous and pistachio resins, myrrh, and other spices (Papageorgopoulou et al. 2009).

The anatomist's period

The “anatomist's period of embalming” ranges from early medieval Europe through the Renaissance with the growing impact of scientific developments in medicine and a consecutive demand for anatomical cadaver studies. Medieval embalming practices included evisceration, soaking the body in alcohol or vinegar, insertion of salts and aromatic herbs into the body cavities and previously incised soft tissues, and finally wrapping the body in tarred or waxed sheets (Brenner 2014). The contemporary physicians Peter Forestus (1522–97) and Ambroise Paré (1510–90) were among the earliest to document such methods. Leonardo da Vinci (1452–1519) also described methods used to preserve the cadavers he studied. His embalming fluids contained turpentine, camphor, oil of lavender, vermilion, vine, rosin, sodium nitrate, and potassium nitrate. Other prominent anatomists and physicians like Bartholomeo Eustachi (1520–74), Reinier de Graaf (1641–73), and Jan Swammerdam (1637–80) have reported similar procedures. By the seventeenth century, the practice of embalming corpses in Europe had become widespread and canonical (Giuffra et al. 2011). A representative description is the brief orientation “*la façon d'embaumer les corps morts*” in “*La Grande Chirurgie des Tumeurs*” (Lione 1657) by the physician Jean Vigier (1600–59).

“All the bowels and viscera must first be discarded, except for the heart, which must be washed with brandy and sprinkled with saline powders, and then placed in a lead box, and given to the parents or friends of the deceased. The entrails and the marrow of the brain will be removed after having opened the (body) parts, and they will be buried. Along the arms, shoulders, the back, the buttocks, thighs, legs, and particularly, at the location of the great veins and arteries, incisions will be made to let out the blood and humors or moisture, which would (otherwise) putrefy. After the incisions have been made, the whole body should be washed with

sponges imbued with brandy and strong vinegar After the incisions, the internal cavities, and the whole body have been thoroughly washed, it is necessary to carefully wipe all the said parts with tow, sponges, or cloth, and then to fill the said incisions and cavities with a powder containing the following: absinthe, marjoram, sage, route, lesser knapweed, mint, laurel, rosemary, lavender, pennyroyal, coloquintide, aloe, common salt and potassium alum. The incisions and cavities being stuffed with the said powder shall be sewn, and the whole body also anointed After the body has been anointed, it will be covered with the said powders, then wrapped in a shroud, and finally in a well waxed cloth, and, sewn in it will be placed in a leaden coffin, filled with sage, mint, heather, marjoram, absinthe, rosemary, red roses, cloves and other dry aromatics. If the dead man is poor, he will be washed with salt water, vinegar, or with lye of oak, fig and grapevine, in which these herbs will be boiled, then he will be wiped with sifted ashes, and the incisions, once dry and clean, together with the cavities will be stuffed with common salt”

Before the introduction of modern chemical preservatives like carbolic acid, phenol, or later formaldehyde, the preserving agents predominantly used in the anatomies were thus alcoholic solutions of arsenic or alumina salts.

Vascular injection of these substances is only rarely reported, however, before the mid-eighteenth century. Frederik Ruysch (1638–1731) is thought to have embalmed by injecting a mixture of pig's blood and the chemical preservatives Berlin blue and mercury oxide into the vascular system (Driessen-Van het Reve 2006). A well-documented procedure, developed by Jean Nicolas Gannal (1721–83), was based on injection of aluminum sulfate or aluminum chloride into the vascular system, in addition to the at the time still customary practice of incision, evisceration, and disinfecting surface treatment. However, it provided satisfactory preservation only for a limited period of time (Gannal 1841). The embalming procedure of Italian anatomist Guiseppe Tranchina (1797–1837) is probably the earliest one documented to involve arterial injection of arsenic solutions without previous evisceration of the body. Among British physicians and anatomists to practice embalming by

arterial injection of different solvents (mainly turpentine) and essential oils (chamomile and lavender) were William Hunter (1718–83) and his brother John Hunter (1728–93) and Matthew Baillie (1761–1823) (Brenner 2014).

Modern tissue preservation techniques

In the course of the nineteenth century, French, Italian, and British scientists refined their injection techniques, permitting the preserving fluids to infiltrate every part of the cadaver. With the advance of embalming by arterial injection, research for new preserving agents directed the anatomist's interests to the field of chemistry. Also starting in the mid-nineteenth century, the embalming procedures begin to separate into those performed as part of mortuary practice and those for diagnostic and scientific purposes, with different aims in terms of presentation and long-term preservation. In the New World, the American Civil War led to a drastic increase in funerary embalming practices, as a result of members of the military dying far from home and the necessity to bring their remains back for local burial. The prevention of the spreading of disease was a further motive behind funerary embalming at that time. Phenol, after its discovery by chemist Friedlieb Ferdinand Runge (1794–1867) in 1834 and its later introduction as a surgical antiseptic (5% aqueous solution of phenol) by Sir Joseph Lister (1827–1912) in 1865, became widely appreciated for its bactericide effects and was introduced to anatomical embalming by Sigismund Laskowski (1841–1928) in 1886. Alternatively, 8-hydroxyquinoline (Chinosol), which at that time was also used to treat diarrhea, was used in the same manner by anatomist Paul Schiefferdecker (1849–1931). The discovery of formaldehyde by the German chemist August Wilhelm von Hofmann (1818–92) in 1869 and the discovery of its tissue-fixating properties by Ferdinand Blum (1865–1959) in 1893 essentially mark the beginning of modern embalming. Within a few years, numerous medical schools throughout Europe introduced formaldehyde to preserve biological and anatomical specimens. Its unfavorable effects, such as irritations of the skin and the respiratory system, conjunctivitis,

and headache, were already known at the time. Nowadays, neutral buffered formalin (NBF), equivalent to 4 percent paraformaldehyde in a buffered solution plus a preservative (methanol), preventing formaldehyde from converting to formic acid, is most widely used to preserve biological tissues. However, fixation techniques have also been developed for more specific clinical and diagnostic applications, such as the method introduced in 1992 by the Austrian anatomist Walter Thiel (1919–2012), which uses a mixture of boric acid, ethylene glycol, ammonium and potassium nitrate, chlorocresol, sodium sulfate, and formaldehyde. It provides excellent color preservation and preserves the soft tissues' flexibility, making it very valuable for surgical training (Thiel 1992). Another fairly recent development is the preservation method developed by Gunther Von Hagens in 1978, and it is currently used in both teaching and research. His so-called plastination method consists of a slow replacement of tissue fluids and partly also tissue lipids by polymers under vacuum, resulting in clean, dry, odorless, and very durable biological specimens. Remarkably plastination leaves the radiographic density of tissues unchanged.

In daily clinical practice, cryopreservation and embedding in paraffin are the two most widely used ways to preserve human tissues, especially for histological analysis, where the preparation of thin sections, which are mounted on glass slides and stained to demonstrate normal and abnormal structures, is to this day essential for microscopic analysis.

The use of human tissue and human remains presents per se an ethical dilemma. In the course of history, anatomists, physicians, and even archaeologists often engaged in activities, even if considered immoral by the public. Today, embalming and preservation of human tissues and whole bodies is needed and widely used for diagnostic, medico-legal, scholastic, scientific, and funerary purposes. In all of these fields, specific ethical and sanitary aspects have to be respected and existing guidelines must be obeyed. In 2014, for instance, the International Federation of Associations of Anatomists (IFAA) established good practice recommendations regarding the donation of human bodies and tissues for anatomical examination. While such guidelines and public awareness are widely

established for modern human remains, analogous codes of conduct must be employed for ancient human remains as well. This ethical debate should consider various aspects such as informed consent but also the degree of intrusion or destruction in relation to an expected scientific outcome.

Fibers

ERICA J. TIEDEMANN
Independent Consultant, USA

KATHRYN A. JAKES
The Ohio State University, USA

Fibers are the components of yarns and textiles. They are recognized by their long, fine shape and are typically found in combinations of some sort; individual fibers are barely visible to the naked eye. Their chemical composition and molecular arrangement give them unique properties of flexibility, strength, and resilience.

Prior to the twentieth century, humans used a wide range of naturally occurring fibrous materials. There are three groups of natural fibers that are classified on the basis of their chemical composition: cellulose (from plants), protein (from animals), and mineral (asbestos).

Cellulose, the building material for plant cell walls, is a linear polymer. Cellulosic fibers grow in plant stems, inner tree bark, leaves, and seed hairs. The oldest fibers and their dependent technologies relied on long fibers found in the stems, inner bark, and leaves of plants. Plant sources vary by region. Some examples are flax (*Linum*), hemp (*Cannabis*), ramie (*Boehmeria*), linden (*Tilia*), cedar (*Cedrus*), paper mulberry (*Broussonetia*), abaca or banana (*Musa*), sisal, and henequen (*Agave*). Flax, domesticated about 10,500–9,000 years BP and used for seed oil as well as for fibers, was one of the agricultural founder crops in the Levant (Weiss and Zohary 2011). The short seed hair fibers of cotton (*Gossypium*) came into use more recently, with independent domestication (see DOMESTICATION) events in the eastern and western hemispheres.

Protein fibers include keratins in the form of mammalian hair or wool and avian feathers, as well as fibroin filaments or silk made by moths in the domesticated *Bombyx* and wild *Antheraea* genera. Humans have gathered tufts of fibers from the landscape during annual molts, or have

plucked, combed, and shorn them from animals such as sheep, goats (see SHEEP AND GOATS), and camelids (see LLAMAS AND ALPACAS). Animal domestication (see DOMESTICATION) led to an improvement in fiber properties, for instance the development of finer wool fibers in sheep (*Ovis aries*). Wool appears in the archaeological record around 5,000 BP, long after the domestication of hairy, wild sheep.

Fibers of asbestos suitable for spinning and weaving break away from chrysotile mineral formations. Accounts from the Mediterranean basin and China describe it as a lustrous and fireproof novelty more than 2,000 years ago (Cameron 2000).

Human-made fibers were developed in the latter half of the nineteenth century, beginning with the regeneration of natural cellulose. In the process, wood pulp or another cellulose source is chemically altered in order to dissolve the polymer and extrude it into long, lustrous, cellulose filaments. Twentieth-century chemists invented synthetic polymers using petrochemicals as a starting point; human-made fibers exceeded 50 percent of the world's total fiber production per annum by the end of the twentieth century.

Small fragments of fibrous materials in the archaeological record offer a window into the minds, landscapes, and seasons of past peoples. The acquisition of specific fiber resources, whether gathered, cultivated, or herded, reveals human relationships with fiber sources and suggests an annual schedule of activities. Evidence of higher fiber technologies such as fiber improvement, dyeing, spinning, and textile formation points to the maker's process, the intended end use of an object, and a cultural accumulation of specialized knowledge. Patterns of fiber use give insight into past ways of life, economic relationships, and group identity.

Identification and analysis

Optical microscopy (see OPTICAL MICROSCOPY) (OM) is the principal tool used in fiber examination.

Brightfield and polarized light techniques provide multiple pieces of information from the examination of a single fiber that cumulatively contribute to fiber identification and classification and to the characterization of fiber condition. With OM, observers can see surface morphology and internal morphology as well as evidence for molecular arrangement.

Scanning electron microscopy (see SCANNING ELECTRON MICROSCOPY) (SEM) shows the distinctive surface morphologies by which some natural fibers can be identified. Energy-dispersive analysis of X-rays (EDS) is often combined with SEM to offer complementary information on elemental composition (see SEM-EDS AND MATERIAL ANALYSIS). For example, SEM displays the characteristic morphologies of siliceous and calcareous inclusions in plant cells called phytoliths, while EDS provides evidence for the presence of silicon and calcium (see PHYTOLITH ANALYSIS). Spectrometric methods such as UV-visible, infrared (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), and Raman spectroscopy (see RAMAN SPECTROSCOPY IN CONSERVATION) provide information on chemical composition, while combinations of chromatographic techniques (see CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS) with spectroscopy have been used to identify fibers as well as their colorants (see DYES).

Fibers can be dated through accelerator mass spectroscopy (AMS) radiocarbon analysis (see DATING IN ARCHAEOLOGY). New sample preparation methods use very small amounts of material, and the sequencing of methods provides information from a single sample. For example, direct analysis in real time-mass spectroscopy yields compositional data; subsequent AMS analysis of the carbon of the same sample yields a radiocarbon date. Isotopic ratios of elements other than carbon supply additional information: keratin, the protein in animal hair fibers, retains strontium isotopes in ratios that are consistent with the strontium isotope ratio in the environment where the protein grew into hair.

Preservation of evidence

Perishable fibrous materials survive in particular archaeological contexts. Desert and arid cave or rock shelter environments desiccate fibrous organic materials. In the extreme cold of ice and permafrost, they are preserved through freezing. Anaerobic conditions, as found in cold lakes, inhibit microbial degradation. Proteinaceous materials are durable in acidic bog conditions, while celluloses survive in alkaline conditions. Organic fibers persist in otherwise inhospitable burial environments when they are associated with mineral ions that retard microbial activity. Occasionally these ions permeate and replace the fiber structure, yielding pseudomorphs, which retain the shapes of the original item but differ in composition. Fibers that have been charred prior to burial resist microbial degradation and can survive the archaeological context.

Gemstones

SALVADOR DOMÍNGUEZ-BELLA

University of Cadiz, Spain

In the current definition of gemstones we can include a wide range of “gemological materials” or “gems,” precious or semiprecious stones where natural or faceted and polished fragments of a large group of minerals belonging to different classes and compositions and some mixtures of minerals such as lapislazuli are included (Arem 1977), but also some natural materials of animal, plant, or meteoritic origin like amber, jet, or tektites—moldavite—(Rapp 2009), which have been used by humans for ornamentation and personal adornment.

In the classification of gemstones, since for the most part they come from natural minerals, we can see that virtually in all mineral classes of Dana’s classification, modified later during the twentieth century by Strunz and others, some minerals with gemological interest are present. However, the majority of gemological materials belong to the group of silicates, specifically the crystalline and microcrystalline varieties of quartz, opals, and other groups of silicates. Other minerals classed as oxides, phosphates, and carbonates also include some examples of the most important gems used within history.

It is considered that the characteristics that give the gems their special attraction are essentially threefold:

- Beauty, a concept certainly subjective and subject to the whims of fashion, but with objective components, such as color, the geometric crystalline form, shine, transparency, light dispersion, and other optical properties.
- Durability or ability to resist without substantial damage shock and friction with other materials. Thus, the admiration that the ancient felt for the diamond was due not to its brightness, which was only discovered in

achieving its cutting and polishing, but to its great hardness.

- Finally, its scarcity or rarity is valued in a gem, which gives to its owner a sense of power, prestige, and individuality.

Since ancient times, there seems to be a human tendency, manifested in all societies and cultures in which men and women tend to use for personal adornment the most striking, or rarest objects that nature places at their disposal. Although gems are generally high-hardness materials in some cases, gemological mineral materials or substances of medium or low hardness (turquoise, variscite, amber) have been used no doubt because of other properties such as luster, color, aesthetic value, or rarity. From ethnographic studies on populations with lifestyles that have remained since ancient times, this fact may be related to personal vanity, but also very directly with the testimonies of social status, power, or uniqueness of whom carries the valuable object or their supposed magical or supernatural powers.

We know according to archaeological findings that humans have used, recognized, and could carve up to 15 different kinds of “gems,” among which there are many materials of organic origin such as bone-ivory, various shells, coral, amber, jet, and some natural glasses. Since the Paleolithic, some types of minerals or substances certainly have been used as an element of personal or symbolic ornaments. So, amber fragments have appeared in caves with Paleolithic occupation in northern Spain, figurines made in mammoth fossil ivory in Germany (40,000 BC), quartz rock crystals in European Paleolithic sites, and so on.

The presence in the archaeological record of some of these materials in sites far away from their place of geological origin allows us to establish the existence of mobility and routes or distribution pathways, at least since Neolithic times (Querré et al. 2014).

If we make a historical development of the use of the different gemological materials by human societies and their geographical distribution, we will observe major differences and some

similarities in terms of the mineral species or type of substance used. These differences are due to the geological origin of the gemstones themselves, cultural preferences for one or more substances and the historical period that we consider.

To summarize, we can cite some examples relating to the main gemological materials and their use throughout the history of human societies, that we can study through different techniques of archaeometry (Rapp 2009; Edwards and Vandenabeele 2012; Vandenabeele and Donais 2016).

In this respect, we can find examples of gemological minerals utilized almost without interruption from ancient times to the present, and with a wide geographical distribution, almost worldwide. The mineralogical classification of Strunz has been followed (Strunz and Nickel 2001).

Native elements, such as diamond, have been used as gems since ancient times, with increased use after it began to be polished, faceted, and its high brightness observed. The first examples of exploitation appear to be in India, where, in Roman times a true distribution route to the Mediterranean was worked.

Sulphides. Pyrite and sphalerite. Pyrite has had some gemological applications, as occurs in the skulls-mosaic of Aztec times, in Mesoamerica, with turquoise.

Oxides. The main gemstones of this group are aluminum oxides such as corundum (ruby and sapphire), with a large presence in South-east Asia (Burma, Sri Lanka, India, Thailand, etc.) and a wide temporal distribution to long history (Calligaro et al. 1999). Another important mineral is hematite, typical in the Mesopotamian cylindrical seal manufacture. Spinel, rutile, cassiterite, and chrysoberyl are less abundant in the archaeological register (Rapp 2009).

Halides as fluorite, a mineral with a scarce use as gemstone. Some examples of its use especially appear in Roman times, for the manufacture of luxury jars distributed in Europe that, according to Pliny, came from Persia.

Carbonates as calcite, smithsonite, rhodochrosite, aragonite, malachite, and azurite. Calcite and aragonite appear especially in small necklace beads from the Neolithic in Europe, Asia,

Africa, and so forth, but many significant examples of Paleolithic objects such as the Venus of Tursac, France, from the Gravettian period (25,000 BC) can be cited. Malachite necklace beads and pendants have been found in native societies of South America, Africa, and Europe; also in large vessels manufactured in the nineteenth century in the Russian Urals (Bukanov 2006).

Sulphates. Gypsum (alabaster), with a very limited use as a gem because of its low hardness, but present in different prestige objects such as second-first millennium BC cups of the New Kingdom, Egypt (Rapp 2009).

Phosphates. Apatite, amblygonite, lazulite, wavelite, and variscite-turquoise. This group of minerals has great interest to societies through time. It is to emphasize the use of variscite throughout the European Atlantic southwest during the Neolithic and Chalcolithic, between 5000 BC and 3000 BC, especially associated with the Atlantic megalithic phenomenon, with ancient mining activity in three areas of Spain and distribution throughout the Iberian Peninsula and France (Querré et al. 2014; Domínguez-Bella 2012). Another phosphate used worldwide as prestige material has been turquoise, blue-green in color, with different geological deposits in the world and in use as gemological material from ancient times to the present. Turquoise objects are remarkable in Mesoamerica (e.g., Aztec) (Cruz-Ocampo et al. 2007) and western North America with highly developed distribution networks over thousands of kilometers (widely used in ancient Egypt, with mining in Sinai and Iran, China, Tibet, etc.).

Lazulite and associated minerals such as calcite and pyrite form the known lapis lazuli, an exploited gem in Afghanistan since ancient times and distributed throughout Asia to the Mediterranean, especially in Mesopotamia and Predynastic Egypt. Very abundant in archaeological records, from China and the Himalayas to the Mediterranean East. The second largest deposit of lapis lazuli, in northern Chile, also used as a gem in pre-Hispanic times by the populations of the Diaguita culture. Other smaller deposits also exist in Burma, Italy, and the former USSR (Bukanov 2006).

Figure 1 Roman intaglio in chrysoprase or *chrysoprasus*. First century AD, Puerto Real, Cádiz province, Spain. Private collection. Photo: S. Domínguez-Bella. (1.07 × 0.83 × 0.53 cm).

Nesosilicates such as olivine, garnets, zircon, andalusite, sillimanite, topaz, staurolite, and sphene. Within this group, olivine or peridot is an important gemological mineral, especially in ancient Egypt, present in Pharaoh Tutankhamen's jewels' that has been mined from as early as 1500 BC and exploited, for example, in its main geological source in the ancient world, the Topazos Island, now known as Zabargad (St. John's Island) in the Egyptian Red Sea, cited by Pliny the Elder in his *Natural History* (23–79 AD) (Lucas and Harris 1989). Also a nesosilicate, and perhaps the most widely used as a gemstone is the garnet, in different varieties, especially red in color widely used in Roman times and as a highly valued gem in the Visigoth-Ostrogoth culture in Europe.

Sillimanite is an important material in the Neolithic and Chalcolithic of the Iberian Peninsula and the Atlantic facade of Europe, for the manufacture of axes and adzes of very different sizes and in some cases, with a nonfunctional use. Its presence together with jadeite in the grave goods of the great megalithic tombs in Brittany confirm this

high symbolic or prestige value. Andalusite (var. chiastolite) is a mineral that because of its peculiar form in crosses has been of symbolic or magical value as a gemstone in northern Spain, from Celtic times to the Middle Ages, and in the Southern Cross Stone in the Araucanian Indians societies of the Patagonia.

Cyclosilicates. In this mineral group, perhaps emeralds and aquamarines are the most appreciated and used gems among history. Within the green stones group and along with other varieties of beryl, the emerald, for its natural geometric shape, brightness, hardness, and color, has aroused a special interest throughout history. It appears in jewelry of ancient Egypt and then in Rome, after the Ptolemaic era, with a wide circulation in the empire from the three known deposits at the time, the mines of Cleopatra in Egypt, Pakistan, and the Austrian Alps. Also in Colombia (Rapp 2009).

Inosilicates. Pyroxene, rhodonite, amphibole. The most remarkable substance of this group is known as jade, formed by jadeite and nephrite minerals, with its main geological outcrops in Central Asia, Guatemala, and the Italian

Alps. In Asia, it was greatly appreciated in the Chinese and Korean cultures, with a use that continues until today, aristocratic tombs of the Han Dynasty (206–220 BC) present numerous and refined objects. Alpine jade, mined in Neolithic times for the manufacture of polished axes that are exported through thousands of kilometers as elements of prestige to great parts of Europe, appearing in numerous megalithic tombs, especially on the Atlantic facade, North Italy, France, central Europe, and so on. Another important area for this mineral is Mesoamerica especially associated with the Olmec, Mayan, and Aztec societies in Mexico and Guatemala, with the main deposits in the Motagua Valley (Guatemala) (Cruz-Ocampo et al. 2007).

Phyllosilicates. Talc (steatite) and serpentine are the two substances of this group with the greatest usage since ancient times. Talc is used in Europe since the Paleolithic times in the elaboration of pendants and small statuettes such as the “Venus of Grimaldi” a green steatite figurine from Balzi Rossi caves, Liguria, Italy. Serpentine records appear in many Neolithic sites of western Europe, also in the Inuk culture of north Canada or in Africa (Zimbabwe).

Tectosilicates. Quartz, opal, xilopale, feldspars, feldspatoids, scapolites. In this group, we can note crystalline, microcrystalline, and amorphous varieties of silica, with wide distribution in time and in many geographical areas (Figure 1). In its crystalline varieties such as rock crystal, amethyst, prase or smoked, the natural crystalline form, generally prismatic, is present in Paleolithic and Neolithic archaeological finds in Europe and North Africa (Domínguez-Bella 2012); and in Protohistory (examples in the Mycenaean culture, and Dynastic era in Egypt) or in Roman times throughout the whole empire, where finely crafted examples appear. In Mesoamerica, spectacular examples of carved quartz skulls are found.

In these latter areas, apart from jewelry, engraved gems and hardstone carvings as in the Indus Valley from the seventh millennium BC vases, bowls, and cups (“*myrrhina vasa*” in Roman times), were highly appreciated as luxury art forms. In the sixteenth to nineteenth centuries the work on big rock crystals was as

well-developed in Europe, in particular sites such as Idar-Oberstein, Germany, with an extractive activity of amethyst and agate from the Roman times to the fourteenth century and a continuous manufacture of gemstones. These objects are present also in India, Tibet, and South Asia.

Organic Materials. Amber, different types of fossil resins generally of Cretaceous to Miocene age. There are different sites in the world that have been exploited since ancient times, as in Paleolithic sites in northern Spain, in the Neolithic of Portugal and southwest Spain, where simetite, a typical Sicilian amber variety, was found (Domínguez-Bella 2012). Amber with a greater dissemination and use throughout history is of Baltic origin, with a use at least since the Neolithic in northern Europe and the establishment of routes from the Baltic deposits to the Mediterranean Sea, from the Chalcolithic to Roman times. Rumanite (Rumania), burmite from the Hukawng Valley in Burma, or copal and amber from Mexico, Colombia, and the Dominican Republic were used as gems.

Coral has a gemological use. Red coral was widely used in the Mediterranean during Roman times, as well as pearls, mother of pearl, and tortoiseshell.

Natural glasses. Obsidian, a volcanic glass widely available in many parts of the world, has had a functional and ornamental use throughout history (Kempe and Harvey 1983). There are multitudes of records of its use from Prehistory in the Mediterranean, North and South America, and especially in Mesoamerica, the Middle East and Turkey, and so forth (Rapp 2009).

Glass and Faience

KARIME CASTILLO CÁRDENAS and
YUAN LIN

University of California, Los Angeles, USA

Glass

Glass is an amorphous solid that, unlike crystalline materials, lacks regularity in the arrangement of its molecular constituents (Figure 1). The glassy state can be obtained through different pathways, but the most common way is the rapid cooling of a liquid under controlled conditions, with an increase in viscosity that prevents crystallization.

Most archaeological and historical glass is composed of a silica (SiO_2) network, a network modifier acting as a flux that lowers the melting temperature of the silica, and a network stabilizer that increases the durability of the glass. The most common source of silica is sand, but quartz and flint can also be utilized. The flux used in glass production varied widely during different periods of time and regions of the world. For example, in the West and Middle East, ashes of salt-tolerant (halophytic) plants which are rich in soda (Na_2O) or potash (K_2O) were predominant ca. 2500–800 BCE. Between ca. 800 BCE and 800 CE, the minerals natron and trona which are rich in sodium carbonates and bicarbonates (and sometimes sulfates and chlorides) were the primary source of flux. After ca. 800 CE, plant ashes returned as the main fluxing material, with the introduction of wood ashes in northern Europe during the medieval period. Calcium oxide (CaO) is a common network stabilizer found in archaeological and historical glass. It can be attributed to limestone or shell fragments (either as impurities in the sand or intentionally added), or through the use of plant ashes. Aluminum oxide (Al_2O_3), another impurity that can be introduced with sand, works also as a network stabilizer. In addition to these three main

glass components, other common additives can include coloring agents such as copper (Cu) and cobalt (Co), decolorizers like manganese (Mn) and antimony (Sb) containing minerals, and opacifiers such as lead antimonate ($\text{Pb}_2\text{Sb}_2\text{O}_7$) and tin oxide (SnO_2) (Henderson 2013).

Glass represents the first manmade translucent solid. It was the last of the three main pyrotechnologies (pottery, metalwork, and glass) to appear, ca. 2500 BCE, in the north of modern-day Syria and Iraq. Initially, it was produced in very small quantities and the earliest objects made were glass beads and other small artifacts (Henderson 2013). The first glass vessels appeared about a thousand years later in Mesopotamia with the invention of the core-forming technique, in which glass threads were spiraled around a clay core that was later removed, followed by mosaic glass, where many pieces of colored glass were fused together and shaped around a core. Blown glass was first developed during the first century BCE in the Syro-Palestinian area and in Italy, soon becoming the dominant technique. During the Roman period, the glass industry became fully established and rapidly spread throughout the empire. Glass technology appeared in the Islamic world since the eighth century CE and the area became famous for its enameling and carving techniques. In the medieval period, glass workshops emerged across Europe that made utilitarian objects following the Roman tradition. Venetian luxury colorless glass, *cristallo*, became highly desirable during the Renaissance, promoting its imitation (*façon-de-Venise* glass), and the development of new glass types such as English lead crystal glass in the seventeenth century (Tait 2004). With the Industrial Revolution, technological innovations greatly expanded the glass industry, some of which included the cylinder process to make sheet glass, and new compositions, such as borosilicate glass, were developed.

Archaeological and historical glass collections are usually studied through typological and stylistic approaches, but classifying glass objects in terms of their formal characteristics

Figure 1 Amorphous structure versus crystalline structure.

(e.g., shape, color, decoration) does not always provide enough information to reconstruct production technology or to develop anthropological interpretations. Crucial information about the material can only be retrieved through scientific methods. Three major approaches dominate the scientific study of archaeological glass: compositional and microstructural characterization, provenance studies, and reverse engineering. Characterization of archaeological and historical glass has proven useful in researching subjects like the technological development of glass production by analyzing changes in raw material selection through time and space (e.g., Brill 1999; Henderson 2013), as well as recycling practices to investigate supply and distribution mechanisms. Characterization is also important to understand the processes of deterioration and to devise ways to conserve glass objects. Provenance studies enable the geosourcing of the raw materials used to make glass and to distinguish between different production groups, making it possible to explore trade networks, and the organization of glass production (Freestone, Ponting, and Hughes 2002). Identifying and quantifying trace elements and determining isotopic signatures are necessary to determine provenance. Differences in trace elements and rare earth elements may represent different raw material sources, while isotope analysis of glass to geosource the raw materials has been focused primarily on the stable isotopes of lead (Pb), oxygen (O), strontium (Sr), and neodymium (Nd) (e.g., Brill 1999; Degryse, Henderson, and Hodgins 2009). Reverse engineering involves the experimental replication of ancient technologies

taking into account characterization and available historical sources, and then the replication products are compared with the archaeological material. Such approach has been applied to better understand glass technology in different contexts.

Interest in the scientific study of archaeological glass is growing worldwide. As more data become available, the study of glass can be performed in a more systematic way and we can begin to look at the larger picture in relation to subjects such as the relationship between organization of production and technological development or the long-distance movement of glass and its associated raw materials within a wider socioeconomic context (Rehren and Freestone 2015).

Faience

Faience is a highly colored vitreous material that consists of a silica-rich body with varying amounts of interparticle glass, coated with an alkaline glaze. Together with glazed steatite and the pigment known as Egyptian blue, it represents one of the earliest manmade vitreous materials. Faience was first produced towards the end of the fifth millennium BCE in the Near East and then in Egypt, expanding later throughout Europe (Tite and Shortland 2008).

The body of a faience object is primarily made with quartz sand or ground quartz. The raw materials commonly used to produce the glaze include crushed quartz, an alkali flux, lime, and colorants. In faience production, there are three main types of flux: soda-rich plant ashes, natron, and mixed alkali. Colorants can

be present in glazes in two forms: metal ions producing transparent colors, and colored particles that yield opaque colors. Examples of metal ions used as transparent coloring agents include copper (blue-green), cobalt (dark blue), and manganese (purple-brown, depending on its oxidation state). Colored particles commonly found in opaque faience glazes are manganese oxides (black-brown), iron oxides (red-black-brown), and lead antimonite (yellow) (Kaczmarczyk and Hedges 1983; Tite and Shortland 2008).

Forming methods of a faience body from quartz paste include hand modeling, shaping over a core, the use of molds coated with lime as the parting layer, and possibly throwing. The faience body can then be glazed using three main methods: application, cementation, and efflorescence (or a combination of these). In the application method, a glazing slurry is first prepared either by direct mixing of the raw materials or by pre-fritting and grinding the mixture. Then the slurry is applied by dipping, pouring onto, or painting the faience body. Once dried, the object is fired and the slurry is turned into a glaze. In the cementation method, the faience body is embedded in a glazing mixture and fired. During firing, the silica in the body reacts with the alkalis in the mixture, forming a glaze over the surface of the body. After cooling, the newly glazed faience object is removed from the partially fused cementation mixture. In the efflorescence method, water-soluble salts are incorporated as raw materials in the faience body. As water evaporates, these salts effloresce on the surface of the body, forming a layer that upon firing becomes a glaze (Vandiver 1983).

Like glass, faience has traditionally been approached through typological and stylistic studies. Although much can be learned by studying faience artifacts in this way, scientific research has greatly enhanced our understanding of this early vitreous material, mainly through characterization and experimental reproduction (e.g., Kaczmarczyk and Hedges 1983; Tite and Shortland 2008; Vandiver 1983). Characterization of faience has mainly focused on the composition of the interparticle glass within the body and of the glaze, as well as on the microstructure of different phases to infer production methods. Experimental reproduction has been carried out extensively, enabling researchers to better

understand faience and its forming technology. In addition, studies focusing on the conservation of vitreous materials have been performed, including faience objects, which are often found in a highly weathered state.

Future directions in faience research may be focused on provenance studies. Some provenance studies of faience glazing materials have been performed (e.g., Kaczmarczyk and Hedges 1983). However, this line of research has yet to reach its full potential. Advancement in provenance studies could shed light on research questions related to organization of production, trade, and exchange within a wider context.

Glass Color

DORIS MÖNCKE

Theoretical and Physical Chemistry Institute, National Hellenic Research Foundation, Greece

Colored glasses were early on valued like gemstones (see GEMSTONES) for their bright colors and later their transparency. The colors have the same physical origin as in mosaic glass tesserae (see CONSERVATION OF MOSAICS), faience (see GLASS AND FAIENCE), glazes (see GLAZES, SLIPS, AND PAINTS), enamels (see CHARACTERIZATION OF METALS AND ALLOYS), and inorganic pigments (see CHARACTERIZATION OF PIGMENTS).

The glass matrix acts as a solvent for dopants (polyvalent transition or rare earth ions). The coloring intensity depends on the sample thickness, concentration of coloring ions, and the transition probability (ϵ) of the valence electrons as they absorb photons from the visible spectrum. The absorbance can be determined by optical spectroscopy. When ϵ is known, the ion's concentration can be quantified from absorption measurements (see optical spectroscopy (see OPTICAL SPECTROSCOPIES) for a schematic of transitions and a list of typical glass colorants and ϵ -values).

Figure 1 shows optical spectra of Co^{2+} (blue) and Mn^{3+} (purple), which are strong colorants ($\epsilon = 200\text{--}135 \text{ L cm}^{-1} \text{ mol}^{-1}$), while spin forbidden transitions of d^5 ions Mn^{2+} (light orange) and Fe^{3+} (light yellow) are much weaker ($\epsilon = 0.3\text{--}5 \text{ L cm}^{-1} \text{ mol}^{-1}$). Charge transfer (CT) transitions from oxygen-anion to metal-cation have much higher transition probabilities (ϵ approximately several thousands), but usually their absorption maximum stays in the ultra-violet (UV) range and only contributes to the absorption edge. The $\text{S} \rightarrow \text{Fe}^{3+}$ transition in reduced melted sulfide-containing glasses lies in the visible range, causing amber to brown color. Intervalence-charge transfer (IV-CT) transitions between two metal cations of different charge, for example $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$ or $\text{Fe}^{3+} \rightarrow \text{Mn}^{2+}$, move further into the visible wavelength region. In glasses,

the ions' proximity for the transfer of electrons is only attained for high dopant concentrations. IV-CT transitions are of similar intensity as CT transitions and glasses with several weight percentage (wt%) of differently charged polyvalent ions often appear black. An anion-anion charge transfer within S_3^- causes the deep blue color in lapis lazuli gemstones.

Optical spectroscopies can resolve multiple colorants: for example, the combination of blue Fe^{2+} and yellow Fe^{3+} ions in green-colored glasses. Many colorful ions were only introduced to glasses in the last centuries: for example, green Cr^{3+} , yellow Cr^{6+} , blue-green V^{4+} , green-yellow V^{3+} , brown Ni^{2+} (purple-bluish in lead silicate), yellow-green UO_2^{2+} (strong fluorescence (FL)), violet Nd^{3+} (FL), and Pr^{3+} (FL). No dissolved ions give a bright red color in glasses. Deep red ruby glasses contain metal colloids, that is, silver or copper nanoparticles, which absorb photons by plasmon resonance. While scattering can be neglected for small particles of less than 50–60 nm diameter, larger particles can induce dichroism or appear opaque (Tilley 2011).

Preparation of ruby glasses is challenging, since ruby glasses are still colorless after melt quenching, containing ionic solutions of Au or Cu ions. The precious metals are reduced to the metallic state (nucleation) under subsequent reheating (often enhanced by redox agents, e.g., organics, Sb_2O_3 , or SnO). Nanoparticles grow upon consecutive heating and since the color depends strongly on the size, number, and shape of the particles, time and temperature of the secondary treatment is crucial. SnO_2 might be added to prevent coagulation of the metallic colloids (Vogel 1992).

Ruby glasses are often so deeply colored that a thin colored layer on a transparent support (flashed glass) is often sufficient. Analogously, thin ruby-red striae serve as vibrant colorant in red church windows (Kunicki-Goldfinger et al. 2014).

A two-step production process is also exploited in silver stained glasses. Silver is not added to the batch, but Ag-salts are painted locally on one

Figure 1 Selected absorption spectra: (a) inter-valence-charge-transfer transition (IV-CT) from sulphide anion to iron ($S^{2-} \rightarrow Fe^{3+}$), and (b) anion charge-transfer of S^{3-} in lapis lazuli. (Stauber et al. 2016); (c to h) d-d transitions in soda-lime-silicate glasses with (c) Fe^{2+} (d^6) broken, and Fe^{3+} (d^5) solid line; (d) Co^{2+} (d^7); (e) Cr^{3+} (d^3) solid line, and Cr^{6+} (d^0) broken line; (f) Cu^{2+} (d^9); (g) Ni^{2+} (d^8); (h) Mn^{2+} (d^5) broken, and Mn^{3+} (d^4) solid line; (i, j) plasmon resonance of metallic nanoparticles (i) Cu^0 and (j) Ag^0 (Perez-Villar et al. 2008).

glass slide. Upon heating, ion exchange occurs between the applied Ag^+ ions and the alkali ions in the glass. Subsequent reduction to metallic silver gives the same reaction as discussed for ruby glasses. For silver particles, the colors range from pale lemon to dark orange (Vogel 1992) (see OPTICAL SPECTROSCOPIES and Figure 1).

In striking or cutoff glasses, the intrinsic UV-absorption shifts into the visible wavelength region, as differently sized Cd-chalcogenides precipitate. Initially, the glasses appear light yellow to colorless, and only controlled reheating and precipitation of nanocrystals induces saturated colors (see OPTICAL SPECTROSCOPIES).

In lead glasses, highly polarizable Pb^{2+} ions shift the absorption edge to longer wavelengths, resulting in a light-yellow coloring. When doped with blue chromophores (i.e., Cu^{2+} or Co^{2+}) a greenish glass color ensues.

In glazes or glass mosaic *tesserae*, colored microcrystalline pigments, such as Naples yellow ($Pb_2Sb_2O_7$) or Egyptian blue ($CaCuSi_4O_{10}$), can act as chromophores. Crystalline pigments can be identified by their fingerprint Raman spectra. The same inorganic pigments known in glasses, glazes, and enamels are also present in many paintings. Because microcrystals cause scattering, such colored materials lose their transparency. Generally, opacification ensues whenever small particles

are dispersed in a vitreous matrix with different refractive index. These particles might be crystalline (e.g., CaSb_2O_6 , TiO_2) or amorphous (e.g., phase separation, air bubbles). Depending on the particle sizes, different types of opacification can be distinguished (see OPTICAL SPECTROSCOPIES).

A different color phenomenon is photoluminescence, as a material emits light of certain wavelengths after excitation with photons. Typical examples include red emission for octahedral Mn^{2+} or green emission for tetrahedral Mn^{2+} . Sn^{2+} , Cu^+ , Sb^{3+} , or Pb^{2+} ions all emit light blue light when excited with UV light. Defined excitation and emission spectra allow the unambiguous analysis of these ions (for more details see PHOTOLUMINESCENCE OF EGYPTIAN BLUE).

Mn ions often affect deterioration (see DETERIORATION OF VITREOUS MATERIALS) and conservation of glasses (see CONSERVATION OF VITREOUS MATERIALS), either through photo-oxidation of nearly colorless Mn^{2+} under UV or sunlight to purple-colored Mn^{3+} , or by microorganisms which transform Mn ions into MnO_2 . Corrosion layers often look white due to light scattering at pores, crystalline salt precipitates, or iridescent

when light is refracted in thin corrosion layers of lower refractive index.

Glazes, Slips, and Paints

MOUJAN MATIN

Wolfson College, University of Oxford, UK

In the field of ceramics, the terms “glaze,” “slip,” and “paint” designate three different types of coating that are applied on the surface of unfired or once-fired (biscuit-fired) ceramic bodies for decorative or functional purposes. This entry provides an overview of the composition and different applications of glazes, slips, and paints in archaeological ceramics and outlines the primary scientific techniques used for analyzing them by reviewing examples of previous studies.

Glazes

The glaze is essentially a layer of glass (see GLASS AND FAIENCE) that provides a smooth, impermeable ceramic surface after firing and enhances the mechanical strength of the ware by the creation of a body-glaze interaction layer (also known as the “buffer layer”).

Chemistry

The structure of glaze is similar to that of glass, and consists of network formers, network stabilizers, and fluxing agents. In archaeological glazes, the principal network former is silica (SiO_2), with alumina (Al_2O_3) playing an important role as the main network stabilizer. Common fluxing agents are alkalis (Na_2O and K_2O), earth alkalis (CaO and MgO), lead oxide (PbO), and boron oxide (B_2O_3). Each flux has its own individual characteristics and largely contributes to some of the primary features of the glaze, such as its firing temperature and its viscosity in the molten state. Hence, the nomenclature used to describe glazes has been based on the dominant fluxing agents present in the glaze composition: for instance, “alkali glazes,” “lime glazes,” “lime-alkali glazes,” or “lead glazes.”

Glazes may also contain metallic oxides as colorants. The color produced by a certain metallic ion depends on various factors, including its positioning in the atomic structure of glaze, the oxidation or reduction atmosphere of firing, and the temperature of firing. The composition of the base glaze also has a direct effect on the coloration of a certain metallic oxide. For instance, copper oxide is a blue or turquoise color in highly alkali glazes, but it becomes green in lead glazes. In reduction, copper oxide tends to black, and in extreme reduction to red. Manganese oxide produces a purple color in oxidization, but tends to brown as the atmosphere becomes reduced. Iron oxide, depending on the conditions, covers a variety of tints from pale green, to yellow/brown, to purple, and black.

“Under-glaze” or “on-glaze” (also “over-glaze”) techniques may be used in the decoration of glazed ceramics. Under-glaze decoration involves the application of paint or slip on a usually, but not necessarily, biscuit-fired body that is then covered with a transparent glaze. The technique is discussed further below under “Slips” and “Paints.” On-glaze decoration, on the other hand, is applied on top of a fired glaze. The ware is again fired, but at low temperatures (usually between 500 and 800 °C), below those employed to mature the glaze itself. On-glaze enamels are formed of a mixture of silica, coloring oxides, and low-melting fluxes, such as oxides of lead and boron. During the enamel fire, the on-glaze colors are fused onto the glazed surface. An example of enameled glazed pottery is the “Minai ware” of Persia which was produced for a short period between the late twelfth and early thirteenth centuries (Wen and Pollard 2016). Luster is another type of on-glaze decoration which was used in the Near East since the ninth century CE and in Europe (mostly Spain and Italy) since the thirteenth century. The production of luster is a complex process that involves painting a copper- and/or silver-containing compound over the glaze and firing under reducing conditions to temperatures between 500 and 600 °C. The ionic exchange between the luster and the glaze layers

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0267

results in a uniform dispersion of copper and silver nanoparticles at the top surface of the glaze, which provides an iridescent metallic appearance (Pradell et al. 2008).

Transparency and opacity are two other important characteristics of ceramic glazes. If fired to the maturing point and fully fused, the majority of glazes will become transparent or nearly so, and the body behind the glaze can be clearly seen. In some other glazes, opacity is a preferred feature in order to completely disguise the color of the body. Three main methods appear to have been used by craftsmen to render less transparent, translucent, or opaque glazes: by underfiring the glaze, by the development of secondary crystals in the molten glaze, or by the addition of opacifiers to the glazing recipe. In an underfired glaze, air bubbles and relics of raw materials remain as undissolved, suspended particles that obstruct the passage of light and thus render translucency. A similar effect was produced by the formation of secondary crystals during firing or slow cooling of a glaze. Both techniques and combinations of them were employed in some of the Parthian (247 BCE–224 CE) and Sassanian (224–651 CE) glazes in the Near East (Pace, Prevot, and Mirti 2008); however, it is not clear whether this was an intentional effect or not. In order to produce a fully opaque glaze, opacifying crystals were added to the glazing mixture. The crystals may have retained their primary structure and remained undissolved during firing, or have dissolved during firing and then recrystallized. In addition to their opacifying effects, these crystals act as colorants. An early application of this technology was in ancient Mesopotamian polychrome glazed bricks, using crystals of lead antimonate ($\text{Pb}_2\text{Sb}_2\text{O}_7$) and calcium antimonite ($\text{Ca}_2\text{Sb}_2\text{O}_7$) to produce opaque yellow and opaque white glazes. From around the eighth century CE in the Levant and the Near East, lead-tin oxide (lead stannate; PbSnO_3) and tin oxide (SnO_2) began to be used in opaque yellow and opaque white glazes. The invention of tin oxide opaque glazes had a major impact on ceramic traditions by providing a fine, smooth, white background over which a variety of colored glazes or other on-glaze decorations could be applied. The technique became prevalent in the Near East from the eighth to the nineteenth centuries CE, and was adopted in Europe from around the thirteenth

to the eighteenth centuries CE, where it gave rise to the production of “majolica,” “faience,” and “delftware.”

Classification of archaeological glazes

The earliest glazes appeared on nonclay bodies. Glazed siliceous stones, such as quartz and quartzite, and glazed steatite were produced from the fifth millennium BCE in Egypt, the Near East, and the Indus Valley. Sometime during the late fifth millennium BCE, the production of so-called Egyptian faience began in the Near East and Egypt. The glazes were broadly of the alkali- or earth-alkali-based compositional types and colored by copper, although some samples of faience have also been found to include cobalt and manganese-iron pigments.

The first glazed clay objects were produced around the middle of the second millennium BCE in the Near East. The composition of these glazes was alkali and remained as such until the eighth/ninth century CE when lead oxide was added to the glaze recipes of the Levant and the Near East. It seems that in all of these cases, the lead oxide was associated with tin oxide for the purpose of glaze opacification. The combined lead-alkali opaque glazing tradition transferred from the Levant and the Near East to North Africa and Europe and continued in both the Near East and Europe until the nineteenth century, when concerns regarding the poisonous properties of lead oxide increased. The first manufacture of lead glazes, however, predates their emergence in the Near East. Lead glazing in China began in the fifth century BCE and became current practice during the Han dynasty (206 BCE–220 CE). Lead glazes were also widespread throughout the Roman and Byzantine worlds.

In the Far East, another family of glazes was developed around 1500 BCE. These glazes were in principle different from those in the Near East in that they matured at higher temperatures (up to around 1300°C) and contained higher amounts of alumina (Al_2O_3). The earliest glazes are believed to have been accidentally fluxed with lime in the form of wood ash from the kiln fireboxes and are thus commonly referred to as “lime glazes” or “wood ash glazes.” Subsequently, lime-rich ashes were intentionally added to the clay by potters

to produce glazing mixtures. The color of early lime glazes was brown to grayish green from iron oxide impurities present in the raw materials. A later development in Chinese glazes took place during the early western Zhou period (1046–771 BCE) when potash (K_2O)- and soda (Na_2O)-rich fluxes and minerals were added to the glazes used on stonewares and porcelains.

Methods of analysis

Scanning electron microscopy (SEM) combined with quantitative elemental analysis has increasingly become the technique of choice for investigating both the microstructure and chemical composition of archaeological glazes. As discussed above, glazes are often inhomogeneous structures due to the presence of undissolved grains, secondary crystals, and opacifying particles, as well as areas of weathering. It is therefore extremely important to study the microstructure of glazes—that is, the shape, size, and distribution of different phases—to reconstruct the technological processes of production and to target specific areas of interest for chemical analysis. Samples are prepared as cross-sections from the glaze layer into the body. This approach enables examination of the body–glaze interaction layer as well as the glaze itself. To give but one example, SEM coupled with energy dispersive spectroscopy (SEM-EDS) examination of early Islamic (seventh/eighth century CE) opaque yellow glazed wares from Egypt and Syria showed that the glazes were of the very high lead compositional type (containing ~60 wt% PbO) and opacified by lead–tin oxide crystals ($Pb(Sn,Si)O_3$). These observations suggested that the production technology of early Islamic opaque yellow glazed wares was likely connected to Byzantine opaque yellow glass-making, on the one hand, and early Islamic opaque white glaze-making, on the other (Tite et al. 2015).

A number of nondestructive methods can also be used for chemical analysis of archaeological glazes. However, because evaluation of the microstructure is not possible with these techniques, there is the risk that the analyzed areas might indeed be parts of the weathered zones or crystalline phases in the glaze. This has to be taken into account when interpreting

data. In the study of early Islamic opaque yellow glazed wares by Tite et al. (2015), portable X-ray fluorescence spectroscopy (pXRF) (see PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)) and particle induced X-ray emission (PIXE) (see ION BEAM ANALYSIS (PIXE/RBS)) (see PIXE AND MATERIAL ANALYSIS) techniques were also used for analysis of glazes from Egypt, Syria, Iraq, and Iran. The resulting data confirmed that the opaque yellow glazes were all of the same compositional type and had adopted similar technological processes.

Slips

The slip, also known as “engobe,” is a mixture of fine-grained clay and water that can be applied to ceramic bodies before firing using two different methods: first, painted directly onto the body using a brush to produce surface patterns that stand in contrast to the background, and second, applied as an overall surface finish to disguise the body by dipping or pouring the slurry over the piece. The first method was a common practice in prehistoric and early historic wares. Elaborate examples of this technique are the ancient Greek black- and red-figure pottery. The iron oxides present in the clay minerals of the slips went through a cycle of oxidizing–reducing–oxidizing in a single firing process, resulting in the black (reduced) and red (oxidized) colors in the final product (Noble 1966).

Application of slips as overall coatings is best represented in the red slip Terra Sigillata wares of the Roman period from North Africa, west Turkey, and Cyprus. From the Early Byzantine period in the eastern Mediterranean, potters began to cover slipped wares with a transparent glaze. Further decorative styles developed by incising through the slip applied to the body before glazing so as to reveal the body beneath. The technique, commonly known as Sgraffito, or Sgraffiato, became widespread from the tenth century CE in the northern and eastern Iranian World and in Fatimid Egypt. In the Iznik pottery of the Turkish Ottoman empire produced from the late fifteenth century, a white slip was used to provide a smooth background for color pigments to be painted before glazing.

Similar to the study of ceramic bodies, the main approach to study slips has been based on their microstructure. Microstructural observations of slips are usually carried out using optical microscopy (see OPTICAL MICROSCOPY). SEM is also used to identify the chemical composition of the inclusions in the slip layer. The application of these methods to study the slips of tenth-century wares from Merv, Turkmenistan, resulted in provisional classification of the wares based on the different microstructures and compositions of the slip clays (Casellato et al. 2007).

Paints

Ceramic “paints” are water- or oil-based suspensions of powdered pigments, generally—but not necessarily—together with fine-grained clay, and an organic binder (see PIGMENTS AND BINDERS), such as vegetable gum or resin, or animal glue. Paints are applied to decorate ceramic surfaces usually using a brush, stick, or the finger. The majority of pigments used in prehistoric and early historic pottery were inorganic minerals that were applied to ceramic bodies before or after firing. Of these, iron-rich minerals were among the most abundantly used for painted decorations in brown (limonite, $\text{FeO}(\text{OH})$), red (hematite, Fe_2O_3), and black (magnetite, Fe_3O_4 , or ilmenite, FeTiO_3). Manganese-rich minerals such as pyrolusite (MnO) were also used for hues of black and brown. For green and blue decorations, copper-rich minerals such as malachite (CuCO_3) and azurite were used. Both pigments become unstable upon heating and were therefore used only on fired ceramic bodies. In addition to mineral pigments, organic pigments were used on fired ceramic bodies: for instance, charcoal for black decoration and burned bone ($\text{Ca}_3(\text{PO}_4)_2$) for white decoration.

Pigments could also be artificially made. The so-called Egyptian blue and Chinese purple are two synthesized pigments of earth alkali copper silicate composition (Wiedemann and Berke 2001). Egyptian blue is the artificial equivalent of the mineral cuprorivarite ($\text{CaCuSi}_4\text{O}_{10}$), which was produced in antiquity by firing a mixture of quartz, lime, a copper compound, and an alkali flux. Egyptian blue paints were more extensively

used in the decoration of tombs and temples and less extensively on pottery. Chinese purple with the formula $\text{BaCuSi}_2\text{O}_6$ is also an artificial pigment with no mineral equivalent in nature. The pigment was used in the paints of the Qin Shihuang's (259–210 BCE) terracotta army and in pottery during the Han dynasty (206 BCE–220 CE). Another well-known artificial pigment is the “Maya blue” which is a combination of indigo, an organic pigment, and palygorskite, a natural clay (José-Yacamán et al. 1996). Maya blue paint was widely used on pottery, murals, and sculptures by the ancient Mayas and other people in Mesoamerica.

Raman spectroscopy (see RAMAN SPECTROSCOPY) offers a unique nondestructive tool for identification of pigments. A number of other instrumental techniques such as X-ray diffraction (XRD), X-ray fluorescence spectroscopy (XRF) (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), and SEM have also been widely used to study pigments in ceramic paints. For characterization of the organic binder, gas chromatography (see CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS) and Fourier transform infrared spectroscopy (FTIR) (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)) have been the two main analytical methods of choice. A combination of these techniques was employed in a series of studies to identify the various pigments and the binding media of the paints applied on China's terracotta army in Xiangshan (e.g., Wei, Ma, and Schreiner 2012).

ICP-MS and Material Analysis

GEORGE D. KAMENOV
University of Florida, USA

ICP-MS instrumentation

An inductively coupled-plasma mass spectrometer (ICP-MS) consists of five main components: an introduction system, a plasma ion source, an ion transfer interface, a mass analyzer (mass separation device), and detector(s). Liquid, solid, or gas samples are introduced in the plasma source via the introduction system. The source of the ICP is a high-temperature (6,000–8,000 K) argon plasma. Samples introduced in the argon plasma are rapidly vaporized, atomized, and converted into positively charged ions. The ions enter the mass spectrometer through a sampler and a skimmer cone. Following the skimmer cone, the beam of ions is steered by the ion lenses of the ion transfer interface into the mass analyzer. The mass analyzer separates the ions based on their mass-to-charge ratio (m/z). The most common type of mass analyzer used in commercially available ICP-MS instruments is the quadrupole mass filter. The quadrupole (Q) consists of four charged rods that generate a dynamic electrostatic field that allows ions of selected m/z to pass through the analyzer and reach the detector. The detection capabilities of Q-ICP-MS can be severely affected by formation of polyatomic interferences. Some Q-ICP-MS are equipped with a collision/reaction cell to break down the spectral polyatomic interferences before the ions of interest enter the quadrupole mass filter. Double-focusing magnetic sector mass analyzer is used in high-resolution (HR)-ICP-MS and multicollector (MC)-ICP-MS. These magnetic-sector instruments use an electromagnet and an electrostatic analyzer to separate the ions based on their m/z . The advantage of the HR-ICP-MS is higher resolution and higher sensitivity when compared to traditional Q-ICP-MS. A specialized type of

magnetic sector instrument, the MC-ICP-MS, is fitted with multiple detectors and is used exclusively for high-precision isotope analyses. The detector converts the arriving ions into electrical pulses. The magnitude of the electrical pulses is directly dependent on the concentration of the element in the sample. The two most common types of detectors used in the ICP-MS instruments are secondary electron multiplier (SEM) and Faraday detectors. Modern SEM detectors provide high sensitivity and very wide ($>10^9$) dynamic range of detection. Faraday detectors are used with high ion signals for high-precision isotope analyses. Q-ICP-MS and HR-ICP-MS are most commonly fitted with a single SEM detector. MC-ICP-MS are fitted with multiple Faraday and SEM detectors.

ICP-MS material analysis

A wide variety of samples, including water, oils, soils, rocks, ores, metals, artifacts, ceramics, construction materials, plants, bones, teeth, fur, and hair, can be analyzed with ICP-MS. As sample molecules are atomized and ionized in the high-temperature plasma, the ICP-MS provides exclusively elemental concentration and/or isotope ratio information. Almost all elements in the periodic table, with some exceptions such as H, He, N, O, and Ar, can be quantitatively measured to sub parts per million (ppm) levels with ICP-MS. Depending on the relative abundances of elements in the samples, the ICP-MS data are reported as major (percent level) and trace (ppm or lower level) elements. It is recommended that sample preparation is performed in a clean laboratory environment with ultra-pure reagents to avoid sample contamination. Different sample preparation protocols are available for ICP-MS analyses. Samples containing silicates, such as soils, rocks, obsidian, and pottery, require digestion with hydrofluoric (HF) acid. Ores, metals, and skeletal material typically require dissolution in nitric (HNO_3) acid. Plants, including archaeological wood samples, can be ashed first and then the ash is dissolved with acids. Microwave

DOI: 10.1002/9781119188230.saseas0315

digestion is also used for organic-rich samples. The most common method for quantification of the results is via external calibration based on standards. Isotope dilution and standard addition are other methods used for quantification of the ICP-MS results. Single or multi-element solution standards or solid materials (rock, glass, clay, bone standards) are available for external calibration.

The concentrations of major and trace elements in archaeological artifacts can be used to provide information about provenance, resources, crafts, and trade in the past. For example, elemental concentrations in pottery and metal artifacts can be used to estimate the type of raw materials, methods of production, and circulation and exchange patterns (see CHARACTERIZATION OF METALS AND ALLOYS and CHARACTERIZATION OF CERAMICS). Trace elements in natural materials such as obsidian and chert can provide information about provenance and trade (see CHERT, SILEX, AND OBSIDIAN SOURCING). Similarly, trace elements in glasses can provide information about their origin and trade patterns in the past (Degryse and Vanhaecke 2016). Elemental analyses of biological materials such as bones, teeth, and hair can be used for estimation of diet (see DIET AND TRACE ELEMENTS), exposure to heavy metals in the past, and postmortem alteration. In particular, elevated concentrations of rare-earth elements and uranium in bones indicate postmortem elemental uptake. Tooth enamel is the preferred material for elemental and isotope analyses, as it is more resistant to postmortem diagenetic changes. The primary composition of other artifacts (e.g., metal or glass) also can be altered due to corrosion and weathering. In addition, an issue a researcher must consider when working with elemental and/or isotopic data is mixing between various sources. For example, metal artifacts can be made with ores from several deposits and/or by recycling of older artifacts (MacFarlane and Lechtman 2014).

Laser ablation (LA) ICP-MS

The ICP-MS can be coupled to a laser ablation (LA) unit for a direct, virtually nondestructive method for spatially resolved (approximately

10–100 microns) chemical analysis of solid archaeological samples (Degryse and Vanhaecke 2016). In this method a small volume of the sample is ablated by a focused laser beam and the resultant sample aerosol is transported by a carrier gas (usually He) to the plasma source of the ICP-MS. Although the ablated area of the sample is micron-sized, the artifact needs to be small enough to fit inside the ablation cell. Alternatively, a custom-made ablation cell can be mounted with adhesive material on the surface of precious artifacts that cannot be subsampled. Although LA-ICP-MS analysis is a virtually non-destructive method for chemical analyses of solid samples, it provides chemical information for a micron-sized area. Therefore, LA can be used for bulk chemical characterization of only homogeneous materials such as glass, obsidian, porcelain, and metals. Bulk composition of heterogeneous materials such as pottery or stone objects is better characterized by dissolution ICP-MS analysis. However, the spatially resolved analysis by LA can be used to “map” elemental distribution within heterogeneous samples. For example, in pottery provenance studies LA-ICP-MS can be used to analyze clay, temper, and glaze components separately and so provide detailed information about the origin of raw materials and method of production. Furthermore, altered, weathered, or corroded areas of artifacts can be avoided by the spatially resolved LA analysis. In addition, LA can be coupled with MC-ICP-MS to obtain in situ isotope information.

MC-ICP-MS isotope analyses

MC-ICP-MS is used exclusively for high-precision isotope ratio analyses. The multidetector configuration allows for simultaneous acquisition of all isotope ion signals for a given element of interest. A number of isotope systems, such as Li, B, Mg, Si, Fe, Cu, Zn, Sr, Ag, Sn, Sb, Nd, Hf, Pb, and U, can be measured with very high precision and accuracy with MC-ICP-MS. Similar to ICP-MS, samples can be introduced in the MC-ICP-MS in solution form or directly as solids via LA. Ultimate precision and accuracy is achieved in solution analyses. It is mandatory that sample preparation for isotope analysis is

performed in a clean laboratory environment using ultra-pure reagents. Following sample dissolution in acids, the element of interest for isotope analysis must be purified by ion-exchange chromatography to remove interfering elements. For example, Sr is purified on “Sr-Spec Resin” to remove matrix and interfering elements such as Rb because ^{87}Rb cannot be resolved from ^{87}Sr even with the highest resolution possible on HR-ICP-MS. In addition to isobaric interferences, the isotope ratio measurement is strongly affected by instrumental mass-bias (fractionation of the isotope ratio due to instrumental effects). If available, an internal stable isotope pair with known isotope abundances is used for fractionation correction. If there is no available stable isotope pair (e.g., Li isotopes), then a standard with known isotope abundances is measured before and after each sample. Then the sample isotope data are corrected based on the standard measurements. A third method for mass-bias correction is via the addition of another element (a spike) with known isotope abundances and close mass to the element of interest. For example, this is the most widely used method for high-precision Pb isotope analyses on MC-ICP-MS. In this method, the purified Pb from the sample is spiked with $^{203}\text{Tl}/^{205}\text{Tl}$ just before introducing the sample in the MC-ICP-MS (Kamenov, Mueller, and Perfit 2004).

In-situ isotope information for solid samples can be obtained directly by LA-MC-ICP-MS. Overall, the precision and accuracy of the LA-MC-ICP-MS isotope measurements is inferior in comparison to solution analyses due to matrix effects, presence of interfering elements, and the large corrections required to calculate the true isotope ratios.

The isotope ratios provide powerful information for identifying provenance, resources, and trade in the past. For example, Pb isotope analyses of metal artifacts, ancient coins, and glaze paints can provide information about the ore deposits mined in the past to extract the metals (Desaulty et al. 2011; MacFarlane and Lechtman 2014). Furthermore, as the isotopes can differentiate one metal supply from another, they also provide information about provenance and trade. Isotope analyses of biological materials such as bones, teeth, and hair are used for estimation of place of origin, mobility, and diet.

For example, Pb and Sr isotopes in human or animal teeth can be compared to known ratios in the bedrock of a given geographical area and this information can be used for identification of the place of origin and migration patterns of the individuals (see MOBILITY AND LEAD ISOTOPES and MOBILITY AND STRONTIUM ISOTOPES). In addition, nontraditional isotopes such as Fe, Zn, and Cu and stable pairs of traditional isotopes (e.g., $^{88}\text{Sr}/^{86}\text{Sr}$) measured with MC-ICP-MS can potentially provide new insights for the origin of archaeological materials and individuals' diet (Knudson et al. 2010; Desaulty et al. 2011). Furthermore, MC-ICP-MS can be used for dating in archaeology by measuring U-series (see URANIUM-SERIES) and U-Pb isotopes (Balter et al. 2008).

INAA and Material Analysis

JOSEPH YELLIN

The Hebrew University of Jerusalem, Israel

INAA is a method for determining the elemental composition of materials by neutron activation analysis (NAA) in a purely *instrumental* manner that requires no chemical preparation of the material to be analyzed. The capabilities of INAA are unique and uniquely suited for relating archaeological materials to geographical/geological areas. Most data available today on archaeological material such as pottery and obsidian are based on INAA. There is a vast literature on the use of INAA in the fields of archaeology, agriculture, biology, chemistry, cosmochemistry, forensic science, geology, medicine, nuclear chemistry, and more generally, material science.

The analysis of material for the concentration of elements by NAA dates to 1936 and is attributed to George de Hevesy and Hilde Levi. They were able to identify elements through neutron-induced radioactivity. Developments in nuclear technology, the accumulation of data on the nuclear properties of the elements and their isotopes, the development of the energy-dispersive germanium detector, coupled with digital computers and software for spectrum analysis, all made INAA a powerful analytical tool for element detection and quantification for material, including the chemical “fingerprinting” of basalt, clay, faience, flint, glass, limestone, marble, obsidian, pottery, pumice, gemstones, and precious metals.

The salient characteristic of INAA for determining element concentrations is that no chemical preparation of the sample is required. There are few or no matrix effects arising from the interaction of gamma-ray photons with the sample matrix. Many elements exhibiting different chemical behaviors can be measured simultaneously. Errors can be precisely calculated, with

outstanding inter-laboratory comparability and intra-laboratory reproducibility.

The amount of material needed for analysis by INAA is typically 100–200 mg, but excellent results can be obtained with smaller samples. Samples are subjected to neutron irradiation in a nuclear reactor and subsequently withdrawn for measurement.

As applied to archaeological artifacts, neutron activation almost always refers to activation by “thermal” neutrons. The term “thermal” refers to the fact that these neutrons have a kinetic energy distribution with a mean energy of 0.025 eV, corresponding to a temperature of 293 K (20 °C). The source of the neutrons is the fission that occurs in the reactor fuel ($^{235}\text{U}_{92}$). Fission neutrons have a mean energy of approximately 2 MeV, but high-energy neutrons are not as effective in sustaining the chain reaction as are thermal neutrons. The neutron energy is reduced by scattering in a moderating material that surrounds the nuclear reactor core. Through multiple scattering in the moderator, the neutrons lose most of their energy and come into thermal equilibrium with the moderator. While most of the neutrons are thermalized, there is a significant number of neutrons with higher energies, and these can be utilized in INAA involving a different type of reaction than that with “thermal” neutrons.

The “thermal” neutrons undergo neutron capture reactions in which the nucleus of an atom absorbs a neutron. If the newly-formed isotope is radioactive, its decay is accompanied by the emission of gamma rays, and so the atom can be detected through the associated gamma-ray spectrum which is unique to every nucleus. Thus every element can be identified and quantified, providing only that neutron capture results in a radioisotope whose decay is accompanied by the emission of gamma rays. An example of a neutron capture reaction that makes cobalt (Co) easily detectable is:

The first gamma ray (γ) after the arrow in reaction (1) appears with the neutron capture and is characteristic of the nucleus formed by the neutron capture ($^{60}\text{Co}_{27}$). This prompt gamma ray forms the basis of an analytical method known as prompt gamma-ray INAA. To utilize the prompt gamma rays, neutrons are extracted from the nuclear reactor and directed at the material under analysis. This method may be used to analyze archaeological objects nondestructively. The second gamma ray after the arrow (γ') in reaction (1) appears with the disintegration of the radioisotope formed by neutron capture, and is characteristic of the resulting isotope ($^{60}\text{Ni}_{28}$). This delayed gamma ray is the basis of what is usually meant by INAA as applied to archaeology. The β^- (beta ray) is the electron emitted by the radioisotope.

A small percentage ($\sim 1\%$) of the neutrons in a reactor have energies in the range 0.025–100 eV. These epithermal neutrons can be absorbed by some nuclei and they form the basis of epithermal NAA (ENAA): this is INAA based on the delayed gamma rays following epithermal neutron capture.

The high-energy tail of the neutron energy distribution has a small but significant number of high-energy (>1 MeV) neutrons. These neutrons cause a nuclear reaction in which a neutron goes into a nucleus and a nucleon (proton or neutron) is emitted, as, for example, in reaction (2) below, where n is the incoming neutron, p is the outgoing proton and γ is a prompt gamma ray:

Analysis of material based on the gamma-ray spectrum associated with high-energy neutrons is called fast neutron activation analysis (FNAA). Fast neutrons can be extracted from the nuclear reactor and directed at a target that can then be analyzed nondestructively. If the element formed by a reaction such as (2) is radioactive, delayed gamma rays (γ') will also be present as in (2), and thus some FNAA (as well as ENAA) always accompanies “thermal” neutron INAA.

The great advantage of INAA by delayed gamma ray is that the activation and measurement processes are spatially and temporally separated. The gamma-ray spectrometry can be carried out in a low background environment

away from the nuclear reactor site. Furthermore, the time of measurement can be chosen to optimize the precision for particular sets of elements, based on the half-life of the radioisotopes involved.

The concentration of an element is related to the intensity of the gamma ray associated with that element. The smallest concentration of an element that can be measured by INAA depends on the intrinsic physical properties of the nuclei participating in the reaction, the natural abundance of the isotope capturing a neutron, the complexity of the material and external factors, such as the properties of the detector system, and the neutron flux. Many trace elements present in archaeological materials can be measured routinely by INAA with a precision of $\ll 1$ $\mu\text{g/g}$. As many as 73 elements (major, minor, and trace) can be measured by INAA.

In order to deduce the absolute concentration of an element from the gamma-ray intensity it is necessary to employ standards of known composition that are neutron-activated simultaneously with and under identical conditions as the samples under analysis. The absolute accuracy depends on the accuracy inherent in the standard. An alternative to the use of a multielement standard is the comparator method. Multielement standards are employed in most archaeological studies.

The first INAA applications to ancient ceramics were reported in the mid-1950s at the Brookhaven National Laboratory (USA). In the mid-1960s a high-precision INAA program was undertaken at the Lawrence Berkeley National Laboratory (USA). Other INAA provenance programs followed (Speakman and Glascock 2007).

An example of an early and important success of INAA in elucidating the origin of pottery was reported in 1973 and involved Palestinian bichrome ware. This pottery, which appeared in the second millennium BCE, was long thought to have originated from the coast of ancient Palestine. INAA showed that the pottery actually originated from Cyprus (Artzy, Asaro and Perlman 1973).

M. Parker conducted excavations in Jerusalem (1909–1911) and his findings were debated for decades. In particular, a small black and red burnished bowl from a tomb presented archaeologists with a paradox that was debated for

nearly a century. While most objects in the tomb could be dated to the late fourth millennium BCE (Early Bronze I) and were locally made according to stylistic considerations, the bowl, by scholarly consensus, was judged to be a Cypriot import on the basis of style. But the style of the bowl belonged to a different age, about a thousand years later (Middle Bronze I), than other objects in the tomb. Unraveling this mystery had important implications for understanding foreign relations in the Middle Bronze I. A study involving INAA provided unequivocal proof that Parker's controversial bowl was locally made and had no bearing on Cyprus (Maeir, Yellin and Goren 1992).

A further example of how INAA can resolve issues of pottery origin concerns the Chariote Krater of Tel Dan (Israel), so-called because the krater is decorated with a chariot procession. The krater was found in a tomb along with other objects that dated the tomb to the fourteenth century BCE on stylistic grounds. For many years there was a debate as to the place of origin of similar pictorial pottery, with the focus on the Aegean area or Cyprus. It was also suggested that the krater was the work of a specific painter whose work was found in Tell el-Ajjul (Israel), Maroni (Cyprus), Miletos (Turkey), Lalyos (Rhodes) and Berbati, Mycenae (Greek mainland). INAA of the Tel Dan krater placed the origin in the Argolid (Yellin and Maeir 1992).

INAA is a most powerful tool in relating obsidian artifacts to their geological sources. Such studies have thrown light on ancient trade and exchange networks in the Near East (Perlman and Yellin 1980), the Americas (Glascok, Speakman, and Neff 2007), and elsewhere.

Gemstones, such as turquoise and jade, have been analyzed by INAA (Weigand, Harbottle, and Sayre 1977; Bishop, Sayre, and van Zelst 1983), as well as precious metals (gold, silver). However, relating precious metals to their sources by INAA is very problematic as precious metals are reworked, melted and mixed, and therefore lose their geochemical signature of their origins.

INAA has been applied to limestone and marble with varying degrees of success. Trace element concentrations in these materials are very low and often at the detection limit. However, multivariate statistical methods applied to limestone compositions have made it possible

to identify common sources, and in this way reconstruct limestone sculpture from fragments in widely different locations with significant benefits for art history (Holmes, Little, and Sayre 1986).

Basalt, flint, and pumice are all amenable to analysis by INAA, as is faience and glass.

Ink

LARS KRUTAK

Museum of International Folk Art, USA

The portability, potency, and lasting permanence of ink have made it a preferred communication, therapeutic, and punitive device by cultures around the world since its invention in antiquity. In Neolithic Europe, ink derived from soot is known archaeologically as a substance used in therapeutic tattooing practices dating to the third millennium BCE (Deter-Wolf et al. 2016). In ancient China and Egypt, a legacy of ink production exists for writing, painting, and tattooing, which allowed secular and religious information to be shared across time and space.

Several contemporary scholars attest that Chinese philosopher Tien-Lcheu (also Tien Chen) invented writing ink in 2697 BCE, but ancient texts do not record the event and this modern construction is contradictory to known historical facts (Laufer 1926, 4). Notwithstanding, historians believe that ink was simultaneously invented in Egypt and China between 3000 and 2500 BCE. The earliest Chinese inks were manufactured from pine soot mixed with a thickening agent, such as animal skin gelatin. Han Dynasty (206 BCE–220 CE) records describe the usage of ink pellets, balls, ink cakes or inksticks, which allowed for easier transport, handling, counting, or consumption when utilized as a medicine (Laufer 1926, 22–23). Much later, during the Northern Song Dynasty (960–1127 CE) are documented recipes for oil soot ink, but recent archaeological discoveries from the Astana necropolis indicate that ceramic lamps dated to the first half of the seventh century CE contain the earliest samples of oil soot ink stock, perhaps for use in local tomb paintings (Shevchenko et al. 2017). Ink was also used very early in Chinese history to mark criminals. The *History of the Former Han Dynasty*, completed in 111 CE, describes 500 crimes punishable by tattoo during the Zhou Dynasty (1046–256 BCE).

Black ink suitable for writing was introduced to Tibet from Indic sources in the seventh century BCE. However, many ancient Tibetan books were written with colored inks derived from mineral sources, like gold, silver, cinnabar, and vermillion. These colors were associated with specific religious virtues and characteristics: Gold is for wonder, wealth, and opulence; red is for alarm, power, and resolve to control one's personal capacities and command of knowledge and wisdom, and so on (Helman-Ważny 2014). Tibetan writing inks were usually contained and transported in brass ink pots. In neighboring India, where the earliest deciphered epigraphic inscriptions date to the fifth to third centuries BCE, ceramic ink pots dating to the first century CE have been recovered archaeologically.

Tamgas, or animal brands and property marks that evolved into dynastic signs and emblems, appeared among early nomadic Eurasian cultures (Sarmatians, Massagetae, Alans) more than 2,000 years ago. One of the earliest tamgas, a square jade ink stamp, dates to the Warring States Period in China (475–221 BCE) and was used by Xiongnu rulers as a seal of office (Tezcan 2010, 384). Among the Mongols, the tamga was originally associated with a tribe or clan, but it later evolved into a seal of state, legitimating the empire as one of law and order. During the Il-khanate period (1256–1350 CE), several ink colors were used with tamgas to indicate the status of the owner. Use of the wrong color was punishable by death. The Nenets of Siberia applied tamga tattoos to their bodies, but these practices ceased in the twentieth century (Rudenko 1929, 16).

The first Egyptian writing inks were created by burning organic materials to form soot mixed with a binder, such as Acacia tree gum, which kept the carbon particles from settling and served to fasten them to paper. The nonfading slurry was used on papyrus paper, of which the first examples containing text are preserved in administrative documents dating to Dynasty 4 (ca. 2500 BCE) (Capua 2015). Early black ink scripts have also been found on ancient ostraca, pottery shards, or limestone flakes, in Egypt and throughout

the Fertile Crescent. Another predominant color seen on early papyrus, tomb walls, and objects of material culture is “Egyptian blue,” the first artificially made pigment, produced by heating quartz sand, copper, burnt lime, and an alkali like natron. Scanning electron microscopy/energy dispersive X-ray spectrometry studies have identified the earliest documented use of this pigmented ink, which occurs on a Dynasty 0 (3250 BCE) alabaster bowl incised with hieroglyphs filled with the blue frit (Corcoran 2016). Red inks derived from hematite also appear on early Egyptian papyri. The color was used in titles and headings to distinguish them from other hieroglyphic text.

Tattooing inks, presumably from soot, also mark the bodies of ancient Egyptian mummies. New observations using infrared photographic imaging extend the temporal range of known examples to the Pre-Dynastic, including a male and female mummy from Gebelein that possess figural tattoos. Accelerator mass spectrometry (AMS) radiocarbon testing has dated both of these bodies to 3349–3018 cal BCE, roughly contemporaneous with the Neolithic “Iceman” of Europe (Friedman 2017).

Over time, writing ink and the use of papyri spread from Egypt throughout the ancient Mediterranean, since writing on paper was of fundamental importance to recording historical, philosophical, economic, and governmental information. The Roman author and philosopher Pliny the Elder (23–79 CE) carefully described the carbon-based ink utilized in his time. But recent 3D phase contrast tomography has revealed that Greco-Roman papyri from Herculaneum preserved during the eruption of Mount Vesuvius in 79 CE contained metallic ink partially composed of lead, which previous studies had identified as being introduced only in the fourth century CE (Brun et al. 2016). Colored inks were also employed in Roman times, usually by the elite. For example, fifth-century CE Roman law mandated that only emperors could write with highly prized purple ink manufactured from charred marine molluscs in the family Muricidae. Anyone who obtained and attempted to use this expensive colored ink faced the death penalty.

Punitive tattooing with ink (*stigmatias*, “marked slave”) was also commonplace in the Greco-Roman world, and perhaps the first

reference to this form of disfigurement was recorded in a sixth-century BCE poem fragment by Asius of Samos. Other sources document this procedure among the Persians and Romans, with the practice continuing into the late ninth century CE of the Byzantine period. Interestingly, as early as the fourth century BCE, references to tattoo removal appear, with the most descriptive account provided by the sixth-century CE Roman doctor Aetius, who also notes the methods and substances used for applying punitive tattoos.

Across the indigenous world, tattooing inks have been produced for millennia. Numerous recipes were utilized and many were believed to possess magical properties that were passed on to the tattoo client. Perhaps the oldest archaeological evidence for tattooing in North America is a 3,500-year-old Paleo-Eskimo ivory maskette from Devon Island, Nunavut. This naturalistically carved female face displays numerous linear tattoos that were similarly worn among Canadian Inuit women until recently (Krutak 2014). Across the millennia, tattooing ink in the Arctic was quite uniform in composition, consisting of lampblack, lubricating seal oil, and human urine which reduced suppuration. Magical referents were attached to the sooty liquid, which was believed to repel evil spirits and the sicknesses they bring.

For more than 1,000 years, across Indochina, tattoo masters (*ajarn*, *khru sak*, Thai) employed magical inks in a very complex and elaborate system of body marking. Many of the inks are personal recipes believed to possess special protective qualities due to their unusual ingredients. For example, some *ajarns* in Thailand, who are often Buddhist monks, use charred and ground sandalwood steeped in herbs or white sesame oil to impart protection. Liquids extracted from wild animals, such as the bile of tigers and bears, and even cobra venom, are mixed with ink for empowerment. The exfoliated skin of a revered *ajarn* monk added to ink mixed with holy water is thought to imbue the tattooed with qualities that engender reverence and respect in the people they interact with (Krutak 2012, 14).

Contemporary studies of ancient ink are revealing profound insights into the technology and socio-historical contexts concerning its production and usage. At the same time, however, advances in scientific research have demonstrated

novel ways to incorporate this time-worn material into modern technological applications, while also providing new insights into ink conservation best practices. For example, it has been found that Egyptian blue emits near-infrared rays when irradiated with visible light, suggesting a variety of modern applications in telecommunications (e.g., a substitute for infrared beams), printing, and biomedical imaging as a nano-ink. Through use of nondestructive investigative techniques like micro Raman spectroscopy, X-ray fluorescence spectroscopy, and infrared photography, it has become easier to authenticate and stabilize manuscripts by identifying the chemical and structural properties of ancient inks. “Fingerprinting” these ancient inks also enables researchers to map their characteristic traits along chronological and geographic axes, which is exceedingly important since many ancient manuscripts lack a recorded archaeological context or provenance (Ryholt 2016).

Instrumental Analysis of Lithics

CHRIS LOENDORF and CRAIG FERTELMES

Gila River Indian Community Cultural Resource Management Program, USA

Archaeologists employ a variety of scientific instruments to study lithic raw materials, including stones that were used to make flaked and ground stone tools. This research is primarily focused on the identification of source locations for raw materials. Researchers have employed diachronic and synchronic patterns of source utilization to study such things as trade relationships, territories for migrant populations, inter-regional contacts including migration, common routes of travel, ritually important items, patterns of social interaction, the value or quality of items, and other aspects of human behavior. However, in order to reliably pinpoint raw material source areas it is first necessary to prove the provenance postulate, and sourcing studies are only possible if the compositional variation between sources exceeds differences within raw material outcrops.

Provenance postulate

Locating a raw material source for any artifact depends on identifying one or more physical or chemical characteristics that are unique among possible source areas. The identification of distinctive variables can be difficult due to a number of factors, such as the dispersion of compositionally similar materials across extensive areas. Alternatively, materials may only outcrop within small areas, but they may be compositionally heterogeneous and therefore difficult to reliably differentiate. Thus, a prerequisite of any instrumental sourcing study is the evaluation of the

provenance postulate for the material of interest. This postulate states that artifact sourcing analyses are only feasible if the compositional variation among source areas exceeds, in some recognizable way, the differences within each of them (Weigand, Harbottle, and Sayre 1977, 24).

Evaluation of the provenance postulate requires identifying potential sources of raw materials and then sufficiently sampling them. Geological maps and studies produced by geologists that report outcrops of formations that include the stone type of interest are one of the primary resources that archaeologists employ to identify possible source locations. While some geochemical data may be available from previous geological studies, it is often necessary to visit potential source areas and collect samples for analysis. There is no set standard for sampling source areas, as sample size and scope are dependent on the material's natural distribution and compositional variability, as well as cultural factors including distribution and consumption patterns. For example, obsidian provenance analyses can be conducted using as few as ten specimens from each individual geological source area because the chemical composition of glass is highly homogenous (Shackley 2005). In contrast, studies of compositionally heterogeneous materials such as basalt, chert, ocher and turquoise require many more samples to assess both within and between source compositional variability. Because of these factors, both archaeological and geochemical patterning must be considered when determining sufficient sample sizes for assessing the provenance postulate.

There is no single ideal analytical instrument for investigating the provenance postulate, and the choice of approach depends on multiple factors. First, some analytical techniques are more expensive and/or not as widely available (e.g., thermal ionization mass spectrometry (TIMS)). Second, compositional variation among source areas may be mineralogical, chemical, or isotopic in nature and this affects the choice of approach. Third, different instruments are variably sensitive to lithic constituents. For instance, instrumental

neutron activation analysis (INAA) can reliably detect parts-per-billion (ppb) quantities for some elements. However, it is not as reliable as energy dispersive X-ray fluorescence (ED-XRF) for identifying parts-per-million (ppm) concentrations among the trace elements that are most commonly used for lithic provenance analyses (i.e., Rb, Sr, Y, Zr, and Nb). These five rare earth elements are referred to as “fingerprint” constituents because although they occur in low concentrations, they are commonly present in igneous stones and their prevalence generally varies among individual outcrops (Shackley 2005). A related issue is that some techniques are incapable of identifying constituents that are common in lithic raw materials. For example, silicon dioxide is one of the most abundant compounds that comprise the rocks on the surface of the earth, but ED-XRF is incapable of identifying oxygen and only has limited sensitivity for silicon. Consequently, multiple analytical instruments may be necessary to fully identify and understand compositional variation among lithic source areas. Because of these issues, it is essential that archaeologists thoroughly review the various analytical techniques that are available before selecting an approach.

Sample preparation and treatment are also important considerations when selecting an instrumental technique. Some analyses can only be completed through the destruction of the artifact prior to or during analyses, whereas other approaches can be undertaken with no permanent damage to archaeological remains. For example, ED-XRF can be conducted with or without damage to the sample. For homogeneous materials such as obsidian it is possible to collect ED-XRF data from unmodified archaeological samples without damaging them in any way. However, in order to calculate elemental concentrations for heterogeneous materials or items of unknown composition, it is necessary to reduce the sample to a fine powder and then further homogenize it by compacting into a pellet and/or vitrifying it. While it is generally possible to conduct destructive analysis of natural stone from geological outcrops, ethical and legal issues may limit any analyses that cause damage to the archaeological materials. Consequently, archaeologists may not be able to employ some techniques that work well for geological sourcing, and these

source geochemical data may be of little use if it is impossible to collect similar information from cultural remains.

A final consideration is that some analytical techniques can only be completed in a laboratory (e.g., INAA, scanning electron microscopy (SEM), and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS)), while portable instruments are available for some types of analysis including XRF. The fully portable nature of ED-XRF instruments allows applications for archaeological materials that would be otherwise impossible. Examples of such applications include the analysis of pictographs, and the collection of compositional data for in-situ architectural stones or other undisturbed archaeological remains. The comparatively low cost and widespread availability of ED-XRF devices, combined with the potentially nondestructive and fully portable nature of the analysis has led to the recent widespread application of ED-XRF to archaeological lithic studies. In some cases, however, other instruments may be better suited to prove the provenance postulate for a given raw material, and researchers should study and understand the strengths and weaknesses of different instrumental analytical techniques.

Archaeological research issues

Much of the archaeological research on lithic source locations has been directed toward questions associated with settlement strategies, especially the degree of sedentism. For example, “some researchers believe that non-local raw materials are more likely to be found on shorter duration sites than on longer duration sites” (Andrefsky 1998, 219–20), and lithic raw material diversity is similarly suggested to be associated with occupation length. Colin Renfrew (1977, 72–78) suggested the “law of monotonic decrement” to describe the negative correlation he observed between distance from the source and the quantity of material, and lithic researchers generally expect that stone abundance should decrease with distance from the source. In addition to decreasing in quantity, studies have demonstrated a relationship between source

distance and cortex percentages on artifacts, and a general tendency for greater reduction of stone from distant locations (Odell 2003, 196). Some researchers have used perceived distance decay relationship deviations to infer territorial areas for mobile groups. For example, Goodyear (1989) observed that many Paleo-Indian sites in North America have substantial quantities of nonlocal lithic material from up to 200 km away, and he argued that the distance to these sources indicated the size of the band territory. Variations from expected distance relationships are also sometimes argued to indicate that a raw material had a special ritual or social significance (Kooyman 2000, 147).

For many reasons, lithic source analysis literature has focused on research issues associated with mobile hunter-gatherers, and in situations where a fully sedentary settlement pattern is apparent or assumed, archaeologists often assert that raw materials from distant sources (e.g., those further than a day's travel) arrived at sites as the result of trade relationships. In order to demonstrate that trade or exchange occurred, however, researchers must address three primary issues (Odell 2003, 209). First, it is necessary to reliably establish the source of raw materials. Second, the manufacturing location for the product must be identified. Third, the mechanism for material displacement needs to be established. While analyses of the first two factors have often produced widely agreed-upon results, demonstrating the third aspect has proven more difficult and controversial. For example, some researchers have argued that the presence of unworked exotic raw materials indicates that direct access existed to source areas, whereas finished goods of non-local materials at a site that lacks manufacturing debris are taken as evidence for trade. While the latter may be possible evidence for trade, the former does not necessarily indicate direct access to source locations, because raw materials as well as finished products can be exchanged (Loendorf, Fertelmes, and Lewis 2013).

Although examination of distance decay relationships is employed to suggest different mechanisms for material transport, analytical problems exist when comparing archaeological data with hypothetical distance relationships. Some major issues include the following. First, this approach requires data from many sites,

but archaeologists rarely have information from contemporaneous components that are also spread uniformly across the landscape at evenly varying distances from a given source. More often, data from just a few or even one site are available, site data may cluster in groups at similar distances, and/or sites at varying distances are from different time periods. Second, different raw material acquisition mechanisms are not necessarily mutually exclusive, and multiple approaches may have been taken even at a given moment in time. Third, the slopes of distance decay correlation lines are related to many variables, including such things as transport costs (i.e., transporting goods over land versus water, or with human porters versus pack animals), in addition to the nature of trade or exchange interactions. Another factor demonstrated by Brantingham's (2003) simulation of lithic raw material acquisition is the effect of raw material density and distribution in the environment on both material diversity at sites and distance decay relationships. Despite these limitations, examination of the relationship between material quantities and distance to the source provides useful information regarding the movement of goods on the landscape.

Sourced lithic types

One common application for instrumental analysis is the identification of source locations for flaked-stone raw materials, especially obsidian. Obsidian is readily sourced using fully portable ED-XRF devices, and it can even be conducted on noncollection archaeological survey projects. Basalt, including fine-grained and vesicular varieties, has also been successfully sourced in different regions using ED-XRF. Because of their compositional heterogeneity, it is difficult or impossible to prove the provenance postulate for most chert (i.e., flint or jasper) and chalcedony (i.e., agate) varieties, though some researchers have had success separating macroscopically similar varieties of these materials by examining fluorescence patterns under ultraviolet light.

Other types of lithic raw materials that archaeologists have attempted to identify source

locations for include stones that were predominantly employed to manufacture ornaments and were commonly transported across comparatively long distances, including materials such as turquoise, chrysocolla, jet, steatite, and argillite. For example, multiple analyses undertaken in the past half-century have attempted to identify consistent compositional variation among the turquoise deposits in the greater southwestern United States (Weigand et al. 1977, 24). However, researchers have identified a number of logistical and analytical obstacles, including several key issues: (1) biased sample selection of archaeological turquoise; (2) intrasource compositional variability of turquoise varieties; (3) an insufficient understanding of intersource compositional variability; and (4) lack of adequate source sampling in some regions.

Archaeologists have also used instrumental analyses in an attempt to identify source locations for lithic pigments that predominantly consist of softer stones, such as ocher, malachite, azurite, and limonite. One of the main applications for pigment identifications and sourcing has been in rock art research. Pictographs were created using a variety of naturally occurring pigments including ocher (to produce purple, brown, red, or yellow), charcoal (for black), and kaolinite (to produce white). Ochres are among the earliest pigments used by humankind. They are derived from naturally tinted sediments that contain iron-bearing minerals. Mineralogically, ochers are generally intermixed with other minerals such as quartz, clays, gypsum, or mica. In addition, ancient potters may have intentionally added materials to ocher to act as binding agents that served to facilitate and prolong the fastening of paint to stone surfaces, and/or as extending agents to reduce the amount of pigment that was required. Therefore, the chemical composition of pigments may be unique in both space and time, making it theoretically possible to distinguish among different ocher sources and/or different paint recipes using instrumental analysis.

Magnetic Tapes

STEFAN SIMON

Yale University, USA

Audio and video records on magnetic tapes form an essential part of twentieth-century cultural heritage, representing the memory and identity of societies in the diversity of world perspectives. The conservation of magnetic tapes is a global challenge with a tight timeline. Presto (2001) found (in a study covering 4 million hours of content) that 70 percent of audio, video, and film contents are at immediate risk from obsolescence of formats and equipment, tape decay, and damage to carriers. Considerable volumes of records, estimated at 200 million hours, are at stake and will need to be digitized within the next 15–20 years or be lost irreversibly.

A major risk facing magnetic tapes is the general lack of awareness among collection stewards, resulting from the fact that their deterioration is not easily apparent. Global disparity further aggravates the “digital divide” between North and South, compromising equal access to the collective memories of the world. Increased efforts to build better physical infrastructure for the storage of sound collections at low temperature and humidity conditions are critical (Library of Congress 2012).

In the discussion about value and significance in magnetic tape conservation, the content is given priority over the original, tangible representation of the object. However, there are also specific aspects that need to be considered when the handling of the original is discussed.

Analog audio and video recordings on magnetic tapes need to be digitized; content from digital carriers needs to be moved into files by digital to digital transfer. A major challenge of this process is to manage the quality through cycles of encoding, decoding, and reformatting and to preserve the connected metadata.

In order to ensure sustainability, new technical solutions for long-term preservation and access

will require considerable human and financial resources, as their needs are different from traditional library and archive materials.

Digital audio files are today's accepted format for analog recordings. By their nature, their preservation needs active management, including data migration and solving obsolescence issues, including the development of new technologies. “Preservation is the totality of the steps necessary to ensure the permanent accessibility—forever—of an audiovisual document with the maximum integrity” (Edmondson 2004, 20). The concept of “maximum integrity” is reflecting the current ethics in conservation and means that the new master should contain as much of the quality of the original as is technically feasible. Each new recopying of a magnetic tape, video, or audio generates a loss in signal, with video tapes being more problematic than audio tapes, due to their existence in a wider breadth of incompatible and short-lived versions.

While this entry focuses on magnetic tapes, it is important to note that tape recording technology actually is based on two independent components—tape and recorder, both susceptible to decay, and each with specific preservation challenges.

History of magnetic tapes

After magnetic recording of sound was demonstrated in 1898 by Valdemar Poulsen, the German–Austrian engineer Fritz Pfleumer (1881–1945) was granted in 1928 a patent for using thin paper coated with lacquer-bound iron oxide powder for sound recording.

Based on Pfleumer's research, AEG Telefunken (Berlin) developed in 1935 the “Magnetophon,” a recorder that used a carrier of cellulose acetate foil, coated with a lacquer of cellulose acetate-bound iron oxide. Magnetic tapes came into wider use in the 1940s after the development of electrical amplification and improvements in fidelity. From the mid-1950s onward, home audio recorders were developed, and in the 1960s cassette formats appeared on the market.

Figure 1 Recording a Fourier transform infrared spectroscopy (FTIR) spectrum in ATR technique for a magnetic tape.

Source: © Rathgen-Forschungslabor, Staatliche Museen zu Berlin.

The technology has been widely used and adopted as the reference, with no major modifications for decades except for the materials used. The twentieth century saw a rapid succession of formats being first developed and then quickly abandoned, an impressive chapter in the history of polymers in conservation.

Magnetic tape is also the oldest memory medium for computers, used for the first time to record data in 1951 in the Mauchly-Eckert UNIVAC I computer. From the mid-1950s onward, magnetic tape was also used for video recording.

Today, the early recordings on wire, steel ribbons, paper, or cellulose acetate tapes with low coercivity constitute only a very small part of the audio/visual archive collections. Practically all audio-specific magnetic tape formats are today out of use, as audio recording and storage became part of the digital world with its specific formats.

Composition of magnetic tapes

Magnetic tapes consist of three components: magnetic particles and binder, combined in the magnetic layer, capable of “storing” the

sound by magnetism impressed on them by the recording head, and a base film/backing, which provides structural support. All three components can be individual sources of decay and failure (Schüller 2008). Microscopy and scanning electron microscopy with energy dispersive spectroscopy (SEM-EDS) material analysis of cross-sections clearly reveals the layered structure of the tapes.

Spectroscopy, specifically attenuated total reflection (ATR) infrared absorption spectroscopy, provides a powerful tool for analysis of the base film and magnetic layer (Gómez-Sánchez, Kunz, and Simon 2012). The low penetration depth of ATR ensures that both sides can be analyzed independently (Figure 1).

Base film/backing materials

In the sequence of the development of magnetic tapes, paper, cellulose acetate, polyvinyl chloride, and polyester (polyethylene-terephthalate) were used. Cellulose acetate has been in use for backing from the “Magnetophon” onwards until the 1960s and 1970s. Adapted from the film industry, it replaced unstable cellulose nitrate

films as so-called safety film. While many tapes recorded at the “Reichsrundfunkgesellschaft” are still playable today, cellulose acetate may over time become brittle and shrink. This deterioration process is highly dependent on storage conditions. High humidity and temperature levels further add to deterioration, and inadequate mechanical handling is another damage factor.

Polyvinyl chloride tapes, produced mainly in Germany between 1944 and 1972, are not known to experience significant chemical deterioration. Polyester, which has gradually replaced cellulose acetate and polyvinyl chloride backing from the late 1950s onward, is mechanically and chemically also quite stable.

Magnetic layer

The first widespread magnetic pigment used was ferric oxide ($\gamma\text{-Fe}_2\text{O}_3$) which was used for all open reel audio tapes, compact cassettes, and the first video formats. It is chemically stable. In comparison with iron oxide pigments, chromium dioxide (CrO_2), and metal particulate (MP) pigments such as barium ferrite particles, provide a higher tape signal output and permit higher recording frequencies, but are more prone to decay.

Pigment binders

The binder is used to bind particles within the magnetic layer onto the backing. Higher magnetic particle density requires lower binder quantity but sufficient binding properties. Many tapes from the 1950s and 1960s have polyvinyl chloride binders.

The majority of tapes from the 1970s onward use polyester-polyurethane and poly(ether-urethanes). Also, copolymers of vinylchloride, vinylacetate, and vinylalcohol, and copolymers of vinylchloride and acrylonitrile have been reported as binders.

Finally, certain additives are added to the binder: lubricants for reducing friction, tension, and tape wear; a head-cleaning agent to limit the formation of head clogs; and carbon black to reduce static charges, which could cause soiling of the tape.

Deterioration processes

Deterioration of magnetic tape occurs in the base film and/or the magnetic layer—within the binder or the magnetic particles. If the binder loses integrity (through softening, embrittlement, loss of cohesiveness, or loss of lubrication) the tape may become unplayable.

The best-described damage processes are those affecting either the base film or the binding media, among them “*sticky shed syndrome*” of the magnetic layer, often attributed to binder hydrolysis, and base material degradation like “*vinegar syndrome*.”

Cellulose acetate tapes become brittle with age and are subject to curling and distortion. Additionally, they can show “vinegar syndrome,” caused by hydrolysis and deacetylation of the polymer. Since the free acetic acid released acts as a catalyst, it is important to reduce the amount of free acetic acid in the environment of the material. There is no linear relationship between physical properties such as tensile strength and the degree of deacetylation.

Affecting mainly modern polyester-polyurethane tapes, “sticky shed syndrome” is a commonly used term to describe the phenomenon associated with deterioration of the magnetic layer (De Lande 1990). The condition causes squealing during playback and deposition of a sticky material on playback heads. This can lead to a significant loss of high frequencies (audio) or a complete breakdown of the signal (video), sometimes leading to collapse of the binder and the complete loss of information.

Problems with sticky tapes generally occur within a few years after production. Not so frequently, tapes become sticky at later stages of their storage, except where they were stored under conditions of high humidity. Not in all cases, hydrolysis of polyurethane (PU) has been made responsible for “sticky shed syndrome,” and a number of other reasons have been discussed as well: One was the exudation of the primer, the often PVC-based binding layer between backing and magnetic layer, or the back coating, respectively. Another one could be the dispersing agents applied to ensure a proper dispersion of the particles within the magnetic layer. Also, lubricants in some tapes, often stearic or oleic acid, which are used to minimize friction, sometimes show

a tendency to be exuded. Because of the higher head-to-tape speeds, video tapes contain more lubricants than audio tapes.

Generally, the playability problems vary significantly between manufacturers and seem to be directly related to the chemical breakdown of the tape binder layer. Next to infrared spectroscopy, gas chromatography–mass spectrometry (GC-MS) is a useful tool to study the causes of tape decay.

Damage in tapes caused by binder hydrolysis are reflected also by a modification of the surface topography. As revealed by confocal microscopy, the mean roughness depth increases with the degree of degradation (Gómez-Sánchez et al. 2011). Due to various chemical formulations and deterioration mechanisms, good markers for condition assessment are related to the tribological behavior of tapes. These markers are surface (surface tension, surface acidity) and mechanical (friction, durability) properties (Prestospace 2006).

Finally, also biodegradation, specifically mold, can affect and damage magnetic tapes. This occurs at relative humidities (RH) of 70 percent and higher.

Preservation strategy

The level of risk for a tape to be lost will depend on its specific vulnerability, its susceptibility to chemical decay, the storage conditions, the quality and availability of replay equipment, and the professional skills of the operators. Archivists often are learning that their professional training has not prepared them sufficiently for dealing with recording media and systems, lack of awareness being a huge risk factor. The small size of many archives with a correspondingly low digitization rate is another issue.

The migration to digital repositories is both expensive and time-consuming. It is important to develop a strategy that takes the individual situation of the collection into account. According to the “Ethics, Principles and Preservation Strategy” established by the International Association of Sound and Audiovisual Archives (IASA 2005) for the safeguarding of audio heritage, priority should be given to those documents that are:

- at immediate risk; and/or
- part of a commercially unsupported system; and/or
- in regular demand.

A good preservation strategy based on conservation triage therefore involves:

- examining the collection, identifying types of tapes, and setting priorities based on their stability;
- understanding the preservation rerecording and how it works, including the transfer technology and migration options across the various media.

A long-term conservation strategy comprises at least three dimensions:

- preservation of the original carrier;
- rerecording of a 1:1 preservation copy;
- creation of an access copy.

Recommended environmental conditions for preservation storage for audio tapes are: 25–30 percent RH $\pm$ 5 percent; 8–10 °C $\pm$ 1 °C; video should be stored separately at slightly higher conditions (18 °C, 35% RH), with secured air circulation. Tapes affected by “vinegar syndrome” should be isolated from the rest of the collection due to catalytic function of free acetic acid on the hydrolysis of cellulose acetate.

Preferable conditions of access storage are closer to the ambient conditions of use: 40 percent RH $\pm$ 5 percent, approximately 20 °C $\pm$ 3 °C. Recent concepts based on the green museum debate advocate for broader margins of humidity ($\pm$ 10 percent) and temperature fluctuations.

In the case of “sticky shed syndrome,” De Lande (1990) recommended as a temporary solution to heat (or bake) the tape at a low temperature for several hours until the oxide readheres, and then copying the recording to a fresh tape. Two alternative methods, the temperature-controlled oven and the microwave oven, are equally useful, 50–60 °C being a sufficiently high temperature, well below the Curie temperature of the magnetic pigments.

The difficulties of transferring video are perhaps even more complex, as most of the video formats had shorter lifetimes and are now antiquated. It is increasingly difficult to

find machines that can play certain formats for migration purposes.

It is also important to create a detailed inventory of the collections, record the physical condition of the material, and define the value and importance of the collection and its contents. Conservation documentation is a key element in this process.

Metallography and Crystallographic Texture Analysis

ARTURO BARBA-PINGARRÓN and
RAFAEL GONZÁLEZ-PARRA

Universidad Nacional Autónoma de México, Mexico

Introduction

Archaeological materials are invaluable to the study of past societies (Pollard and Heron 2008). In addition to the anthropological information provided, an archaeological artifact is capable of revealing the technology used in its making. Use of analytical techniques may help archaeologists to determine the origin of materials used and trade routes, and even if a technology is local or imported.

Metal artifacts sometimes require the use of techniques from different branches of science for their study and preservation. The study of metal artifacts can be carried out by applying relatively simple or more complex methods; for example, the composition of the material can be determined by means of X-ray fluorescence (XRF) or energy dispersive spectroscopy (EDS). With optical microscopy, it is possible to determine the microstructure of the object, hinting at its production process. In addition, corrosion mechanisms must be taken into account for preservation.

One of the major advances in the study of metals and alloys was the discovery that their microstructure was the result of their processing history (Holloway and Vaidyanathan 2010). Even if nondestructive characterization of metals is now possible, from an analytical point of view, whenever possible, it is best to remove a small sample of the metal object and cut, polish, and mount it on resins for analysis. In addition to microscopic examination, this procedure allows further physical examination of the sample. It is

possible, for example, to study the physical evidence left by thermal and mechanical treatments that the metallic alloys were exposed to and determine ancient technological processes (Pollard and Bray 2014).

Archaeometallurgists have been using the metallographic microscope to study compositional phases and structural features that reveal the annealing and work-hardening of metal production in antiquity. Although optical microscopy is a great tool to study metal structure, recent use of scanning electron microscopy (SEM) provides higher magnification and punctual chemical analysis of the present phases (Rapp 2000).

The use of X-rays makes it possible to identify features not easily visible due to corrosion. With X-ray diffraction (XRD) it is possible to determine the grain orientation (crystallographic texture) and crystalline phases present in the metal. With other optical instruments and principles, it is possible to explore what is known as the microstructure of metals and alloys and to observe the phases that compose them, including transformations that they have undergone during their processing and use. In addition, it is possible to gather information about the preservation or deterioration process over time.

With development of instruments currently available in the field of metallography and crystallography, it is possible to obtain information on chemical composition, crystallographic characteristics, and other properties, such as a metallic material's morphology, roughness, surface topography, imperfections, inclusions, and slags.

Metallographic techniques

Metallography consists of the observation of a piece by means of a metallographic optical microscope or scanning electron microscope in order to determine the type and morphology of the microconstituents of the material (Scott 1991). This is of utmost importance and is related to material properties; the proportions in which they are present, for example, reflect the

mechanical, thermal, and chemical deterioration to which the material has been subjected. To carry out this analysis, preliminary preparation steps are required which can be synthesized in the selection and extraction of the samples, their assembly (if required), coarse and fine sanding, and final polishing—leading to a specular appearance on the surface and a chemical etching. With this it is possible to reveal the microstructure, achieving a maximum magnification of the order of 1,000 X.

Metallography can provide valuable information about archaeological metal objects. In the case of ferrous parts, the most outstanding aspects are:

- The presence of slag inclusions, whose volume and shape may provide elements for determining the manufacturing process.
- Identification of the type of alloy and the different phases present.
- Phases that result from the use of heat treatments, for example acicular structures, associated with quenching and tempering, or spherical structures as evidence of materials that were cold-worked and then annealed.
- Evidence of composite parts, generated by joining processes such as welding, for example in sharp tools.
- It has sometimes been possible to detect the presence of carburized zones. Regarding both ferrous and nonferrous alloys, the presence of various phases in the alloys can be highlighted.
- Determination of mechanical forming processes, such as cold-working (through the presence of elongated grains) or cold-working plus annealing (through the presence of equiaxed grains).
- Evidence of casting processes, observing a predominant dendritic microstructure in the material.

With SEM, information obtained with the metallographic microscope can be deepened and expanded. In the case of electron microscopy, an electron beam is used, which, when interacting with the material, produces various radiations through which images can be obtained and the

ordering or information of the chemical composition of the parts detected. Depending on the thickness of the samples and intensity of the electron beam, information can be generated at the surface level and a few micrometers below it (SEM), allowing detailed observation of the surface topography of objects, careful study of the impurities and inclusions of the material, and determination of the chemical elements that in a precise way are required to explain aspects of the manufacturing and metallurgical history of the objects. X-ray radiation can be emitted, the resulting pattern being specific and characteristic of each chemical element. Thus, it is possible to determine—through either EDS or modification of the wavelength (wavelength dispersive spectroscopy (WDS)—the elementary qualitative and semiquantitative composition of the samples.

Crystallographic texture analysis

A basic aspect of common metallic materials formed by grains or crystals is that mechanical properties depend on the orientation of each of these; this is called crystallographic texture. There are three experimental ways to determine texture: (1) XRD, (2) electron diffraction, and, more recently, (3) neutron powder diffraction. The first method can evaluate a relatively large area of the sample (several grains) so that the information obtained is representative of the material. In the second technique, the evaluation is made grain by grain, which allows for greater detail in the study of the texture of the material.

Determination of different textures in a material is useful for knowing their behavior against mechanical loads. The results of XRD, electron diffraction, and neutron powder diffraction can be reflected in pole figures and through the use of orientation distribution functions (ODF), with which it is possible to construct predictive models of the mechanical and microstructural properties of a material (Artoli 2007).

Hardness and microhardness

The hardness test is a very useful tool for the characterization of materials. Hardness values of an empirical nature can be correlated with other mechanical properties such as tensile strength. There are several types of tests, all based on the resistance of the material to penetration by an indenter when a load is applied.

Hardness tests have a relevant field of application when there is sufficient quantity of material (which often does not occur with archaeological material) and with mechanical properties that allow the use of larger loads. They provide a tool, through the evaluation of a general indentation, to obtain a general hardness value of a material, and with that vision they should be applied, because if the sample preparation process is simple, the degree of sensitivity will be lower than that of other types of hardness tests. Microhardness tests (the most common variants being Vickers and Knoop) employ smaller loads than those used in hardness tests; using smaller amounts of material (so that they can be adapted to the conditions of the archaeological material available), it is possible to obtain information on components that can evaluate different sections of a sample.

Sample cases

Some cases that illustrate the application of these techniques can be found in the literature. For example, SEM, XRF, EDS, and XRD have been used; through metallographic studies, it was possible to explain how the corrosion deterioration process of copper ingots was developed, which was considered to be related to the techniques by means of which the copper alloys and subsequent processing technologies used were made (Garbacs et al. 2015). Usually, the corrosion resistance of copper and its alloys is good; however, over very long periods of time, under certain conditions, they may undergo degradation processes of an electrochemical nature. Thus, metallographic study allows us to explain the relevance of grain boundaries as sites of greater chemical activity, associated with the possible presence of segregation, impurities, and crystallographic

imperfections within the grain boundaries themselves. Also, with metallographic study it has been possible to determine the type of corrosion linked to the corrosive medium where it occurred. For example, for copper and its alloys, pitting and intergranular corrosion are most common when the medium is seawater, while general corrosion is usually present under atmospheric and soil corrosion conditions. Another related case (Ashkenazi, Iddan, and Tal 2012) in the study of copper objects and their alloys is the evaluation of 14 bronze artifacts from the Hellenistic period that were characterized by optical microscopy, microhardness, SEM, EDS, and XRD. Because of the metallographic study it was possible to determine that the objects had been elaborated by cold-working processes, and even in some objects, evidence of the development of sophisticated Cu-Fe joining methods was found.

In the study of historical objects of ferrous alloys, a first example is that related to iron pieces located in ships that were shipwrecked (Ashkenazi et al. 2012), in which the techniques of X-ray, optical microscopy, SEM-EDS, and XRF, and measurements of microhardness were used. The connection between microstructure and mechanical properties allowed researchers to conjecture about the use of processes such as hammering and/or quenching in ancestral times. This provides archaeologists with evidence about the ancient manufacturing processes and probable uses of the objects studied, and to estimate their antiquity.

Nondestructive Compositional Analysis of Ceramics

JAYE MCKENZIE-CLARK and
JOHN MAGNUSSEN
Macquarie University, Australia

Identification of the manufacturing origin of goods provides archaeologists with insight into the patterns of trade and economic conditions within past societies. This information is vital to identifying sources of supply and demand in ancient times. Similarly, recognition of how goods were produced furnishes an understanding of the technological sophistication of specific cultural groups, allowing archaeologists to discern changes in manufacturing practices over time.

If the source and manufacturing techniques used in the manufacture of pottery can be identified, ceramics, the most frequently recovered artifacts from ancient sites, have the potential to reveal important information about past societies.

The compositional analysis of pottery provides a fingerprint of the material from which it is made, thereby helping to identify the source of the clay and the workshop location. Today, the ceramic specialist uses a wide variety of techniques to determine the composition of the clay from which pottery is made and to identify the technical capabilities of ceramic producers within ancient societies.

Compositional analysis is usually determined by methods such as petrographic analysis using optical microscopy (OM), X-ray fluorescence spectrometry (XRF), inductively coupled plasma mass spectrometry (ICP-MS), inductively coupled plasma atomic emission spectrometry (ICP-AES), and less frequently neutron activation analysis (NAA). Studies of the technology employed in the manufacture of pottery furnish information on the preparation of clay, and forming and firing temperatures, allowing archaeologists to understand the sophistication

of ceramic production in specific societies. Such investigations utilize a number of techniques such as X-ray diffraction (XRD), differential thermal analysis (DTA), scanning electron microscopy energy dispersive X-ray fluorescence (SEM-EDX), thermogravimetric analysis (TGA), and thermal expansion (TE) (Madrid Fernández and Buxeda i Garrigós 2002).

While these methods have each played an important role in determining the manufacturing source of pottery and identifying the technology employed to make ceramics, this knowledge comes at considerable cost because most of these investigative techniques require the partial or total destruction of the ancient material, resulting in the obliteration of large amounts of historical material. While some analytical techniques, such as petrographic analysis, are considered nondestructive because the majority of the sample in question remains intact, they can be at best considered minimally destructive because the samples need to be removed from the original artifact for testing. In addition, some techniques, such as NAA, render the samples radioactive, which means that contemporary access to the ancient material is severely restricted.

Ideally, the removal of a sample for compositional testing should not affect the structural integrity of the vessel, nor should it impact on the visual attributes of the sherd in terms of the diagnosis of its vessel form. Consequently, it is common to take samples from the base or foot rim of the vessel, because assessment of the vessel shape is usually made by analysis of the rim and wall profile. Once removed, these samples cannot be reinstated. This is an irreversible process.

Furthermore, these destructive techniques are either predicated upon the assumption of complete uniformity of composition of an item or the complete destruction of it to be able to prove otherwise. Sampling error therefore becomes a significant, yet routinely ignored consideration.

To overcome these problems, in 2011 John Magnussen and Jaye McKenzie-Clark developed a nondestructive technique using dual energy computed tomography (DECT) to analyze the

composition of archaeological ceramics. This research was undertaken at Macquarie Medical Imaging, Macquarie University, Sydney, Australia (McKenzie-Clark and Magnussen 2014).

Computed tomography (CT)

The technique of CT is complex and it is important to understand the basic principles of the process before discussing DECT. Conventional polychromatic CT scanners, first employed in the 1970s, use a system of a rotating X-ray tube, opposite a concave, curvilinear array of X-ray detectors. Rays are passed through the object of interest and the attenuation or weakening of the rays is measured as a series of projections on the detector on the opposite side of the object. This information is collected at various angles around the object and it is then possible to reconstruct an image that gives a map of the object in terms of the differing X-ray attenuation.

X-ray attenuation is classically expressed as the Hounsfield Unit (HU) density of parts of an object, wherein 0 HU is water, -100 HU is fat, -1,024 HU is gas, and values > 0 HU range from soft tissue to metal. The maximum value typically allowed is +3,072 HU, which normally represents complete beam attenuation. The values reflect the biologically centric nature of the technique and also historical limitations on data storage (-1,024 to +3,072 is a 12-bit range).

The degree to which the X-rays attenuate is directly related to the composition of the object they are passing through. X-ray attenuation is caused predominantly by a combination of the photoelectric effect and Compton scattering. The former is strongly related to the atomic number (Z) of the material of the object, while the latter relates to electron density, which is proportional to mass density (ρ) for most materials. When using a polychromatic X-ray beam it is not possible to separate the contribution from these two effects. This means that a material of higher atomic number but lower density is indistinguishable from one that has a lower atomic number and proportionately higher density. For instance, a pair of objects in which one has a higher atomic number (due to different minerals) but lower density (due to production techniques) can give

identical HU on conventional CT to those of a lower atomic number but higher density.

A further difficulty when analyzing material using CT scanning is that there is preferential attenuation of lower-energy photons when passing through many substances of interest, resulting in an increase in the mean energy of the beam, an effect called beam hardening. This makes analysis of larger objects more difficult because of the gradual loss of X-ray photons in the beam and a combination of less accurate HU density assessment and, in the extreme, photon starvation, when there are insufficient X-rays that pass through parts of an object to be able to effectively reconstruct its internal architecture.

The usefulness of conventional, polychromatic CT for the accurate characterization of pottery samples is therefore limited, beyond simple determination of three-dimensional shape and gross or comparative measurements of any internal features.

Dual energy computed tomography (DECT)

In contrast, DECT uses measurements from two different energy spectra, thereby enabling a basis material decomposition to be performed for each ray path, and providing the relative contribution from each material to the total linear attenuation coefficient along that path. Using reconstruction techniques, the relative contribution throughout an object can then be calculated for each of the basis materials. Furthermore, the effective atomic number, as well as the effective monochromatic attenuation at a relatively wide range of monochromatic energy values, can be calculated at each point in the material being examined.

The DECT technique not only enables the removal of beam hardening effects but also provides considerable additional information about the material being examined than is possible when using a standard polychromatic beam. DECT allows the monochromatic attenuation at a range of values, the effective atomic number value, as well as the components in the basis decomposition (commonly a water and iodine pair) to be measured throughout an object.

The technique overcomes the historical problems of distinguishing materials of different

atomic number and density; it identifies the component of attenuation from the Compton effect (proportional to mass) and the photoelectric effect, which relates to atomic number (Alvarez and Macovski 1976). Material decomposition into components of significantly disparate atomic number has been shown to be a useful tool for this approach (Kalendar, Klotz, and Kostaridou 1988) and is the one used in this technique, with decomposition into water ($Z_{\text{eff}} = 7.42$) and iodine ($Z = 53$).

Water is chosen as it corresponds to the universally accepted zero value for polychromatic HU values on conventional CT. Iodine is a useful pair because it has a sufficiently high atomic number to give good material separation within the range of substances normally encountered in pottery, as well as being a commonly used CT contrast agent for biological scanning, and has been well characterized on modern CT units.

MicroCT versus conventional CT

Micro- or nanoCT has become more readily available for researchers recently and is characterized by the extremely high-resolution scans that it is possible to acquire, ranging from a few

hundred micrometers down to 50 nm. Its heritage is one of industrial scanning and thus it can often employ higher X-ray energies than available in clinical scanners, reducing the effects of beam hardening, and can even be successfully used for metallic objects.

However, the higher resolution imaging comes at considerable cost, since the field of view is proportionately reduced, sometimes down to $< 20 \mu\text{m}$, and scan times can run into many hours even before reconstruction of images is taken into account. In comparison, the scan field of view for conventional polychromatic CT and DECT is 500–650 mm in diameter and up to 2,000 mm in length, depending upon the scanner used. The scan times rarely exceed 20 seconds, with image reconstruction taking seconds to minutes, reflecting their clinical heritage.

DECT analysis of pottery

Using a GE HD750 (GE Medical Systems, Milwaukee, Wisconsin) 128 slice fast switching, DECT scanner, and pottery from known sources and of specific compositions (Figure 1), the authors compared the accuracy of DECT with the more traditional analytical techniques

Figure 1 Pottery sherds arranged on the bed of the DECT scanner.

of petrographic analysis (OM), ICP-MS, and ICP-AES (McKenzie-Clark 2012).

The total scan time was approximately four seconds, generating in the order of 650 MB of raw data, which were then analyzed using a GE Advantage Workstation and dual energy analysis toolset.

Each individual sample was assessed and a region of interest drawn with a total area of approximately 20 mm², to allow for the measurement of about 50 voxels (volume pixels—the smallest area that the scanner can measure on this reconstruction).

The region of interest was carefully positioned so as to avoid the edges of the pottery fragments, which would lead to inaccurate readings. Where possible, the surface of the sample was also avoided so as to isolate the sample voxels to the fabric, rather than any surface coating material or residue build-up which may have been present.

For each voxel the following values were obtained: polychromatic HU (120 kVp equivalent); monochromatic HU (40–120 keV at 10-keV intervals, nine data series); effective atomic number (Z); material decomposition—water (mg/cc); and material decomposition—iodine (mg/cc). Individual samples were tested in order to assess the sample consistency using a 120-keV HU dataset. In each case the means, interquartile ranges, and outliers were identified, as well as a group analysis. Similar consistency was seen with the other values obtained.

DECT scanning of the ceramic samples established the mean composition as well as confidence intervals and standard deviations for each group. Once again, the example chosen was the 120-keV HU dataset, and similar confidence intervals and standard deviations were returned for the other values obtained.

To test the validity of the analyses, an unpaired t-test was performed between each of the groups. All group comparisons yielded a P-value of <0.001, with actual P-values of down to 10⁻¹²² between the most disparate groups.

To fully utilize the statistical significance of the analysis performed, a minimum cross-sectional examination area was chosen at 20 mm². This provided approximately 50 data points per sample, equivalent to a 5-mm-diameter section of the fragment that is distinct from the surrounding air.

The sample region of interest (ROI) requires at least one nonincluded voxel both above and below the plane of analysis because of partial-volume artifact. Consequently, at a voxel thickness of about 0.5 mm, this requires the ROI to lie mid-way through a sample of at least 1.5 mm thickness. Within the pottery sampled this gave a total of 1,315 data points, with 13 values measured per point, or some 17,000 values for analysis. Within those many measured values, 120 kVp HU was chosen, as it is representative of the most commonly used conventional or polychromatic CT acquisition spectrum.

Results

Analysis of the monochromatic attenuation values generated by DECT allowed intra- and intergroup comparisons to be made, enabling the similarity of samples from each fabric group to be determined. The technique also permitted analysis of the compositional uniformity within each sherd. All vessels were made from one piece of clay, but in each example the composition of the base, or foot rim of the vessel, varied considerably from the rim and wall of the sherd (McKenzie-Clark and Magnussen, in preparation).

This result brings into question the accuracy of traditional compositional analysis where most samples are removed from the base or foot rim because of the need to maintain the integrity of the sherd in order to analyze the vessel form. The results of this investigation indicate that the classification of fabric groupings, established by sampling vessel bases, may not be indicative of the composition of the remainder of the vessel.

DECT scanning also revealed that the density of the clay fabric varied considerably, indicating that the preparation of raw clay by potters and workshops was not consistent (Figure 2). The results suggest that particular workshops maintained stringent standards of clay preparation, while other manufacturing centers took a less rigorous approach. Moreover, in some workshops, considerable differences could be distinguished between the clay prepared by individual potters, suggesting that each potter worked the clay to suit their own preferences and method of

Figure 2 DECT scans reveal marked differences in the density and composition of the clay fabrics.

working (McKenzie-Clark and Magnussen, in preparation).

The compositional results achieved with DECT appear comparable to those generated by previous studies using OM, thin section analysis, ICP-MS, and ICP-AES (McKenzie-Clark 2012; McKenzie-Clark and Magnussen 2014). The results suggest that DECT has the potential to be a viable addition to traditional analytical methods and perhaps an alternative to destructive methods currently employed to analyze ancient ceramics.

Advantages of DECT

DECT scanning provides the composition of ceramic clays in terms of their effective atomic number, thus enabling samples to be compared to group analyses and other individual pieces. Compared with conventional analysis techniques, DECT has significant advantages, including:

- It allows multiple regions of interest to be sampled on each piece of pottery, thereby giving a comprehensive and thorough assessment of the vessel composition.
- Sample size can be controlled to provide reliable comparative evaluations across all objects of interest.
- Clay density throughout a given ceramic sample can be mapped and provides invaluable insight into the techniques of clay preparation used by the original manufacturer.
- During the entire DECT scanning process, the sample materials remain untouched and can be placed in plastic storage bags while being scanned, thereby securing the safety of the objects. This is particularly useful when scanning valuable, delicate, or fragile ceramics.
- Multiple sherds of pottery can be placed on the DECT scanning bed and data acquired in one pass of the machine.
- Scan times are quick (a matter of seconds), depending on the size of the object being analyzed.
- There is no need to retain the ceramics once the process is complete. Once scanned, the ceramic material is not required.
- The scan data can be stored for future study or reference and reinvestigated at any time, without the need to retain the ceramic object.
- Being a digital format, scan data can be readily exchanged globally, with ease.

Most importantly, unlike other analytical methods used to investigate archaeological ceramics, the technique is totally nondestructive. The raw data allow future analysis of the pottery, without the need to physically alter the original

ceramics, thus preserving heritage for future generations.

Acknowledgments

The authors would like to thank Professor M. Pagano, Archaeological Superintendent of Umbria (2013), Carsulae inspector P. Bruschetti (2013), and the Italian Ministry of Culture (Ministero per Beni e delle Attività Culturali) for permitting the ceramic samples to be transported to Macquarie University. We also acknowledge the generous support of Macquarie Medical Imaging and their technical staff, including Simon Bird, in the acquisition of the data and the generation of images for this research.

Ore and Smelting Slag

MARCOS MARTINÓN-TORRES

University of Cambridge, UK

Ores and smelting slag are, respectively, the main raw materials and by-products of metallurgy. As such, they are one of the major research foci of archaeometallurgical studies. The analysis of archaeological ores and slag can yield information about the metals being produced and underlying engineering parameters such as temperatures and redox conditions, the selection and manipulation of natural materials, and the efficiency of ancient technologies. Through large-sample comparative approaches it is possible to use slag analyses to reconstruct knowledge transmission, technological traditions, and their evolution in time and space in response to different environmental and cultural constraints. With comparatively limited curatorial concerns impeding scientific analyses, ores and slag can be among the most revealing material categories in the archaeological record. Their study has progressively become mainstream since the 1980s, after decades of neglect owing to their “industrial” nature and allegedly limited museological potential.

Ores are rocks that contain metals in such condition and quantity that they can be extracted in a cost-effective manner. Given the fluctuations in technology and in the value of metals in time and space, the attribution of a rock or geological deposit to the “ore” category is culturally contingent. Metal-bearing minerals are typically dense and colorful, and as such they have also been used as pigments and medicines or for lapidary work. In these nonmetallurgical contexts, the use of the term “ore” can be misleading and should be avoided.

There are as many ore types as there are rock types, each with their own constraints and potentials. For example, sedimentary ores (hydroxides and carbonates) tend to be near the surface and easier to exploit but smaller, whereas massive hydrothermal sulfide deposits are typically larger

but require higher investment and technological knowledge for mining and smelting.

The analysis of ores in archaeology often seeks to identify the nature of the rocks exploited, their grade (i.e., richness in metal content), and the types of metal-bearing (ore proper) and nonmetal-bearing (gangue) minerals that are geologically associated. These analyses can include a combination of mineralogical (e.g., X-ray diffraction (XRD)), chemical (e.g., X-ray fluorescence (XRF), inductively coupled plasma (ICP)), and microstructural analyses (i.e., by microscopy), together with a broader assessment of the geological context. In addition, ore analyses are useful to facilitate mass balance calculations (see below). Their chemical and isotopic composition can be used as a reference for provenance studies, providing a signature against which those of slag or metals may be compared.

A key challenge for ore analyses in archaeology is that of sample representativity. Often, the richest ore deposits will have been exhausted in the past, and hence those left behind at mines or geological formations are not representative of those that would have been used by the communities being studied. When broken ore fragments are found at archaeological sites, one can be more certain that these were extracted by past people, but the fact that they were discarded rather than smelted may be due to their not being of the desired standard; thus, they may not be representative as samples for grade assessment or mass balance calculations. This is in addition to problems such as the natural variability of geological deposits, meaning that often many samples are required to obtain a reliable characterization. Modern economic geology maps can be useful to identify potential ores used in the past, but archaeologists should be aware that these are likely incomplete: small and rich deposits exhausted in the past and/or lacking economic value in the present (and hence not included in modern maps) may be archaeologically relevant.

Mining was usually followed by beneficiation, which involved the mechanical preparation of the ore by crushing and sorting according to

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0426

physical parameters such as color or density. This process seeks to achieve a material that is consistent and optimized for the subsequent smelting operation, in terms of particle size and composition/richness. Beneficiation sometimes involved a separate heating stage or “roasting” at moderate temperatures to remove water, sulfur, and other impurities as gas, and to increase the porosity and brittleness of the ore.

Smelting is a chemical reaction whereby metals are extracted from ore minerals, where they occur chemically bonded to other elements. In most cases this reaction takes place under temperatures higher than used for domestic or other craft purposes, and under a reducing atmosphere (i.e., one with relatively high carbon monoxide content). This environment is created by the burning of wood charcoal (or, more rarely, mineral coal) in a container such as a ceramic reaction vessel or crucible, or a larger heating structure or furnace (or, more rarely, a pit in the ground). During smelting, crushed ore minerals are made to react with gases so that they release the metal(s) of interest. This reaction can take from less than one hour to several days, depending on the reagents and scale of the operation. Most smelting reactions will lead to the formation of slag in addition to metal and gas. Slag forms as a liquid that contains the bulk of the ore minerals and oxides that were not reduced to the metallic state, in addition to fuel ashes, and molten ceramics from the crucible surface or the furnace inner lining. From an efficiency perspective, ideal slag is well reacted, fluid at relatively low temperatures, and devoid of the metal being smelted, thus ensuring a good separation between product and by-product. However, archaeological slag often deviates from this expectation, potentially reflecting a lack of technological skills, individual cost-benefit assessments that may require compromises on the above ideal in favor of other parameters such as fuel efficiency, or ritual constraints affecting practice.

Most preindustrial slag is dominated by iron oxide and silica, irrespective of the metal being smelted, as these are among the most abundant oxides on the Earth's crust. However, the proportions among these and other constituents will vary depending on their original nature, and parameters such as charge composition, temperature, atmosphere, and duration. As such, slag

constitutes a durable record of ancient technological practice, albeit a challenging one because of the potentially mixed material and behavioral signatures conflating in slag formation. It should be noted that very pure ores can be smelted without producing slag (“slagless smelting;” cf. Craddock 1995), and that some metallurgical processes other than smelting, such as metal refining or iron forging, can produce slag too. In addition, high-temperature industries such as lime burning, pottery firing, and glass making can produce amorphous fused debris that may be confused with metallurgical slag, although the latter tends to be denser because of its higher iron content.

Slag from individual smelts can occur as very small (<1 cm) nodules or vitrified layers lining crucibles from small-scale operations (Radivojević and Rehren 2016), or as large blocks exceeding 100 kg collected at the bottom of furnaces (Humphris et al. 2009)—or anything in between. Archaeologically, slag dumps can accumulate as relatively large scatters or even form so-called slag heaps amounting to tens of meters in diameter and weighing many thousands of tonnes. The morphology of slag lumps can be informative of the type of structure where it formed, and hence of cultural or temporal associations. For example, Late Neolithic copper smelting slag often occurs as very small nodules with sharp edges, resulting from the action of smelters who crushed it to retrieve metal globules trapped within after smelting in a crucible. In so-called slag-tapping furnaces, slag is drained while hot through a hole or arch at the base of the furnace: the resulting slag is typically more homogeneous and preserves tell-tale morphologies which can resemble a flat cake (if it solidified while floating on a pool of metal) or ropey textures such as those of flowing lava (if solidified during tapping). Bowl or pit furnaces will result in larger blocks of slag accumulating at the bottom of the furnace, in addition to amorphous, fist-sized chunks that solidify within the furnace, often in contact with charcoal and preserving impressions thereof. Furthermore, the original metal smelted can sometimes be identified by the corrosion of metal particles within the slag that appear as colored patches in the predominantly black slag; they can be green for copper, red or blue for iron, or white for lead and zinc.

Archaeometallurgists often carry out bulk chemical analyses of slag. These can be very useful not only in identifying the metal being smelted, but also in allowing mass balance calculations. These are particularly helpful when the composition of other system materials such as ores, technical ceramics, or fuel ash can be determined. Different models have been proposed to use these data to assess the efficiency of the operation (e.g., the proportion of metal from the ore left behind in the slag), to estimate the metal output per unit of slag, or to hypothesize the relative contributions of ore, fuel ash, and ceramics to slag formation (Thomas and Young 1999). Combining the slag bulk chemical composition with phase diagrams or other information from modern engineering literature it is also possible to estimate the melting point of the slag and furnace operating temperatures. In turn, these calculations aid in the assessment of how past smelters adjusted charge composition or operating conditions (Rehren et al. 2007). While all of these are estimates which can bear considerable margins of error, they provide quantitative proxies for cultural behavior that permit comparisons in space and time. As such, they can form the basis of studies addressing broader archaeological issues such as knowledge transmission, independent lines of metallurgical invention, or technological adaptations to changing environmental and cultural constraints.

It is essential, however, that chemical analyses of slag are supplemented by microstructural examination, typically by optical and/or electron microscopy (Georgakopoulou, Bassiakos, and Philaniotou 2011). This approach allows an evaluation of the extent to which the slag was fully molten, the presence of residual ore minerals or other particles that may help identification of the original charge, and the nature and composition of the metal left in the slag. For instance, inferences about technological parameters will vary depending on whether copper left in slag is bound in a silicate, as a copper oxide, trapped in a sulfide, or as ferruginous metal globules. When identified under a microscope, the nature and distribution of neoformed phases crystallizing in the slag is also informative of the conditions of slag formation: For example, wüstite (FeO) is indicative of highly reducing conditions suitable for bloomery iron smelting but excessive for copper smelting,

whereas higher valency magnetite (Fe₃O₄) is more compatible with copper smelting but can appear on the outer surface of any slag that was tapped out and solidified in contact with air. Some researchers undertake mineralogical or redox analyses of slag using techniques such as XRD or Mössbauer spectroscopy, but the texture or internal homogeneity of the slag cannot be evaluated without microscopic analyses.

Pioneer studies on archaeological ores and slag in the 1970s focused strongly on identifying early evidence of metal smelting and characterizing technical aspects that reveal past technological achievements. Especially since the 1990s, the scope of archaeometallurgical studies has expanded to cover virtually all metals and periods. Technical studies remain a necessary component, but information is used increasingly to address broader issues such as the social contexts of innovation, the evolution of sociotechnical systems, and metallurgical changes associated with variable constraints. There have also been successful attempts at direct dating of slag by radiocarbon, archaeomagnetic, or luminescence methods (Ben-Yosef et al. 2016).

Paper

BARBARA WAGNER

University of Warsaw, Poland

The term “paper” probably came from the Egyptian word “*papyrus*” used to describe writing material created from stems of *Cyperus papyrus*. A product similar to our modern paper was produced in the second century CE in China. It is commonly assumed that the first sheet of paper was made by a Chinese dignitary, Cai Lun, in the year more or less 105 CE. He watched the production of silk, which included washing the silk wool on special mats. Wetting and whipping silk wool with sticks resulted in leaving residual amounts of fibers on the mats. After removing the cotton wool from sieves, a thin layer of fibers formed specific structures, which after drying could be stored without losing their shape and served as a support for writing or drawing. It seems less clear now, after some Chinese archaeologists shed new light on this theory, pointing out that papermaking might have started even earlier and the importance of Cai Lun relied rather on him being the improver and popularizer of papermaking rather than an inventor (Jixing 2011).

There is common agreement that the use of cellulose fibers from the sap of mulberry, linen rags, or old fishing nets instead of expensive silk was proposed by the Chinese. The main method of paper production has been nearly the same for centuries. It is based on cooking vegetable raw materials in alkaline solutions to weaken bonds between fibers and facilitate slurry creation. Potash or lime solutions were used for this purpose. The fibers were suspended in water, then poured through sieves and delicately shaken to allow random distribution of the fibers, left to drain, pressed to form sheets of paper, removed from the sieves, and dried. The Chinese used milled gypsum as a mineral filler to increase the quality of paper and rice starch for sizing.

The use of different plants and sources of raw materials influenced the properties of created

structures that after drying could serve for writing. The know-how of paper production was kept secret for centuries, including such details as selection of fibers to obtain targeted features of the end product, including thickness (grammage) of the paper. Arabs started to produce paper around 751 CE. Bloom wrote that microscopic examination of medieval Arab papers occasionally reveals unprocessed threads and bits of cloth, indicating that the pulp was made mostly from rags (Bloom 2017). They were ground during time-consuming processes and boiled to form a slurry of fibers. While dried in a form of paper, starch paste was used to size paper sheets from both sides to obtain good writing properties and a fine appearance of the paper surface (Mahgoub et al. 2016).

Around 1100 CE, Italians began to produce paper and introduced water propulsion to drive machines shredding and fiberizing the plant material. Besides the use of hydro power, the first centuries of European papermaking did not bring changes in the production process until the invention of the printing press by Gutenberg in 1440. The search for a faster and cheaper way of paper production began in the first half of the fifteenth century with the rapid increase in the demand for this material. Replacement of the traditional raw materials was needed due to the lack of enough old rags for production. A French scientist, Rene de Reaumur, proposed the use of wood instead. Wood was used as a raw material already in 1769, but the first paper made entirely from wood pulp was not produced until 1840. Significant acceleration of production achieved by introducing paper machines with a continuous wire-mesh belt allowed formation of paper in ribbons instead of individual sheets. With modern machine-produced paper, fibers are not quite accidentally deposited. Most of them are arranged parallel to the direction of the ribbon length. This affects the properties of the end product, particularly with respect to the mechanical resistance of the paper, which is greater along the plant fibers. This is a fundamental difference between machine- and handmade papers, in which all the fibers are arranged quite

accidentally without affecting the mechanical parameters in any direction of the paper.

Although some changes in paper production have been introduced, the main steps are generally the same. They depend on chemical and mechanical processing of plant materials, draining and fiberting on the sieve, and drying and finishing the surface of the final product. Progress in the nineteenth century changed paper production dramatically. Very soon it became apparent that despite the progress in costs and speed of production, paper durability drastically decreased because it was made of wood and sized with a resin glue. Paper durability was limited to only a few decades, while paper produced according to the old technology could be stored for hundreds of years.

Regardless of the form, either sheets or a continuous ribbon, paper is a material made from mutually tangled plant fibers with walls that are made of cellulose (Andreasson, Forsström, and Wågberg 2003). Although paper can contain sizing substances, fillers, and dyes, cellulose determines the basic chemical and physical properties of paper. Thus, paper durability is directly related to cellulose durability, which can be heavily dependent on other substances influencing the rate of cellulose reactions and modifying paper preservation state. While rags were the source of long cellulose fibers, wood was soon recognized as a raw material of much worse quality. Additionally, resin glue used for sizing introduced into the paper structure significant quantities of acidic substances which lower the pH value of paper and were harmful to cellulose. pH is recognized as one of the basic parameters describing the state of paper, and the best value for prevention of deterioration should be neutral or slightly alkaline.

Taking the above information into account, it can be stated that when acidic compounds (resin glue and aluminum sulfate or wood pulp) were introduced in the modern production process of paper, they increased the initial acidity of the products and the syndrome of “acidic paper” became a common problem. The protection of all documents endangered by acidification required development of effective procedures applicable for routine mass deacidification of library collections. Nowadays, various inorganic and organic compounds can be used as active deacidification

agents. They can be applied by spraying, brushing, or immersing endangered objects in respective solutions (Potthast and Ahn 2017). Their effectiveness was tested many times and proved satisfactory for slowing down the chemical reaction responsible for increased paper brittleness.

Chemically, cellulose is a polysaccharide composed of glucose units whose number determines the degree of polymerization (DP). Vegetable fibers are made up of chains of different lengths, having variable DP: Native wood cellulose is characterized by a DP from 6,000 to 14,000, while the DP of cotton cellulose can be estimated as 20,000–30,000. The properties of paper depend on the DP of the cellulose. Breaking down cellulose chains leads to depolymerization of cellulose molecules. Intermolecular binding occurs when the distances between neighboring cellulose macromolecules do not exceed 0.25 nm, allowing formation of hydrogen bonds in so-called crystalline regions. The availability of crystalline areas to chemical reactions is limited. The variety of binding forces of cellulose molecules, as well as different degrees of crystallinity and polymorphism, are responsible for the fibers’ anisotropy. It is expressed in a tenfold higher breaking strength along fibers than in their lateral direction. Conversely, the ability to swell across cellulose fibers is about 200 times greater than in the longitudinal direction. Different fiber orientations in hand made traditional papers and modern machine papers enhance the differences between these two cellulose products.

Reactions between cellulose and reagents may occur simultaneously and depend on the speed of diffusion of chemical compounds into the molecule as well as the course of each reaction. Hydrolysis of cellulose may occur in both acidic and alkaline environments, leading to gradual shortening of cellulose chains (depolymerization). Alkaline hydrolysis requires both high temperatures and concentrated chemicals at the same time, so it is less problematic than acidic hydrolysis. The other problem mentioned quite often in the literature is oxidation leading to mixtures of cellulose molecules with variable degrees of oxidation. These molecules are typically characterized by a lower DP than cellulose, higher oxygen content, poorer strength properties, and higher solubility in alkaline solutions. The final products of degradation of oxidized cellulose

include sugar, and glucuronic and glucaric acids. In antique objects, hydrolysis and oxidation reactions most often occur simultaneously (Havermans and Dufour 1997). Depolymerization of cellulose and further decomposition (degradation) not only occurs due to hydrolysis and oxidation, but also very often these reactions are accompanied by the enzymatic action of microorganisms (fungi, bacteria) or a thermal and photochemical decay.

The quality of paper can be tested by learning about specific parameters including physical (e.g., fold number, folding endurance, tensile strength), optical (e.g., brightness, yellowness), and chemical (e.g., pH, DP) properties. These parameters can be measured by modern instrumental methods and the obtained results allow for paper quality assessment. Some tests of paper quality have been adapted to the needs of conservation research from the modern paper industry, but sampling of contemporary papers does not require a reduction of the size of the samples and can be even completely destructive, which is unacceptable for historical objects. For tests based on destructive measurements, model samples are used. Such model samples reflect basic features of real objects. A huge advantage of using model systems is that they can be subjected to artificial aging and even completely destroyed during investigations of the influence of variable parameters on paper durability (Becker et al. 2016).

Paper Analysis

SATORU TSUCHIKAWA, TE MA, and
TETSUYA INAGAKI
Nagoya University, Japan

Paper has played a key role in recording the development of culture all over the world. It is a multicomponent material that is mostly made from cellulose, with a small amount of organic and inorganic additives. The irreversible deterioration of historical paper is caused by several processes including acid hydrolysis, autooxidation, light, and the presence of microorganisms (María and Hervé 2011). In the conservation field, knowledge of the original morphology and paper surface texture is critical for the paper to be preserved as historical evidence. Because of the conservation value of historical paper, without any sampling or with a very small sampling, rapid and effective analysis methods are required.

To achieve this goal, many spectroscopic techniques have been developed for historical paper analysis such as Fourier transform infrared (FTIR) spectroscopy (see INFRARED ABSORPTION SPECTROSCOPY (IR, FTIR, DRIFT, ATR)), Raman spectroscopy (see RAMAN SPECTROSCOPY), nuclear magnetic resonance spectroscopy (see NUCLEAR MAGNETIC RESONANCE (NMR)), X-ray spectroscopy (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), laser-based spectroscopy (see LASER-INDUCED BREAKDOWN SPECTROSCOPY (LIBS)), inductively coupled mass spectroscopy (see MASS SPECTROMETRY (MS)), atomic absorption spectroscopy, and X-ray photoelectron spectroscopy (see X-RAY PHOTOELECTRON SPECTROSCOPY (XPS)).

FTIR spectroscopy is an analytical technique used to identify molecular components and structures (the energy level of infrared (IR) light corresponds to the energy required to cause molecular vibrations). The IR spectra of a sample is collected by illuminating a beam of IR light on the sample, then using a spectrometer to record how much energy was absorbed (y-axis)

at each wavelength (x-axis). This technique was performed by Casoli et al. (2013) to understand the composition and inorganic filler types of one late-nineteenth-century newspaper. Cellulose pulp, wood pulp, and fillers (calcium sulfate dehydrate, calcium carbonate and silicates, kaolinite) were detected in their study. The results played an important role in the definition of micromorphological properties and roughness of the paper surface. In Zotti, Ferroni, and Calvini's (2008) study, the presence of fungi in biodeteriorated eighteenth-century etchings was verified, and the FTIR spectroscopy technique was used to check the composition of the paper surface. It worked well, particularly after the elaboration of the experimental data which enhances the significant differences in the spectra. This study also supplied further standards for deeper FTIR analysis.

Near-infrared (NIR) spectroscopy has shown its capability to analyze physical and chemical properties of wood-based materials while retaining their structure intact. In the range of 800–2500 nm, there are overtone or combination bands (fundamentals appear in the mid-IR region) due to functional groups such as C-H, O-H, and N-H. Because the molar absorptivity in the NIR range is typically quite small, nondestructive, fast quantitative and qualitative analysis can be achieved without special sample pretreatments. NIR spectroscopy could also be useful in investigating the chemical condition of washi artifacts (literally “Japanese paper,” which has played a vital role in Japanese culture since the introduction of paper from China in the early eighth century). Yonenobu, Tsuchikawa, and Oda (2003) compared the NIR spectra of two samples of antique washi paper with modern materials. They showed that NIR spectroscopy can detect change in the main chemical components of washi paper, since the obtained results were consistent with conventional sugar analysis; that is, the degradation occurs especially in the amorphous region of cellulose where depolymerization is induced dominantly by the peeling of end-groups in polysaccharide and hydrolytic reaction in alkaline conditions, which was also observed by the NIR second derivative change.

Nuclear magnetic resonance (NMR) shows great promise for future use in damage assessment of historical documents. For instance, Blümich et al. (2003) nondestructively analyzed the degradation of historical books dating from the seventeenth century by (NMR) relaxation. A mobile NMR sensor (NMR-MOUSE) was employed, and experimental results indicated that although the sensor works strongly in inhomogeneous polarization, different degrees of paper degradation could be discriminated from the regularized inverse Laplace transform of the envelope of the acquired echo signals. Also, in Viola et al.'s (2004) study, a new portable NMR device was developed to test some aspects of the microscopic healthy state of the historical documents. It used nonionizing radio frequency electromagnetic waves and was easily transportable without hazard to people or the environment. Some pages of the *Codex Major* belonging to the *Collectio Altaempsiana* (1600–10) were examined; the NMR results provided indications of the spread of the deterioration process of the paper and the corrosion effect caused by the iron-gall ink.

X-ray fluorescence (XRF) is an analytical technique that uses the interaction between X-rays and a material to determine its elemental composition; this technique also demonstrates possibilities for detection of nondestructive elements of historical documents. In Manso, Costa, and Carvalho's (2008) study, paper documents from the eighteenth and nineteenth centuries were analyzed by energy dispersive X-ray fluorescence (EDXRF). Strong positive Spearman correlations between Co, Ni, As, and Bi were found in Dutch and Hespe watermarked papers. The concentration levels of these allowed distinguishing between Dutch and Hespe papers.

Several combinations of spectroscopy have been applied to paper analysis. Castro et al. (2008) investigated a Dutch map from the eighteenth century by using EDXRF, FTIR, NMR, Raman, and scanning electron microscopy coupled with energy dispersive spectrometry (SEM-EDS). All aspects of the sample were determined in an elemental and molecular way. The cellulosic support was characterized and its state of conservation was evaluated. Moreover, paramagnetic impurities were detected together with copper metallic chips. The colors present in some areas of the map were analyzed, and vermilion, carbon black, and

organic colorants were found. Barrett, Ormsby, and Lang (2016) undertook nondestructive analysis of 1,578 paper specimens made between the fourteenth and nineteenth centuries to better understand changes in paper composition over time and how these variations might affect paper stability during long-term natural aging. Here, gelatin content and color were determined using ultraviolet/visible/near-infrared (UV/Vis/NIR) spectrometry; residual metals were measured using XRF.

Other advanced methodologies are reported for the study of ancient paper. Gibbs et al. (1997) developed a simple, rapid, high-performance liquid chromatography (HPLC) method. It gave excellent separation of the protoberberine alkaloids and allowed the unambiguous detection of berberine in dyes extracted from tiny fragments with dimensions of 3×1 mm removed from the edge of ancient paper samples. Examination of 25 ancient papers contemporary with the Dunhuang *Diamond Sutra* (the world's oldest dated printed book) indicated the chemical components, including not only berberine but also previously unsuspected yellow compounds of palmatine and jatrorrhizine.

Deterioration of historical papers is caused by several processes, including acid hydrolysis and autoxidation due to the presence of metal ions contained in inks or pigments. Migration of the metal ions into surrounding paper material can cause huge damage to ancient documents. Fluorescence labeling of carbonyl and carboxyl groups in combination with gel permeation chromatography multiple angle laser light scattering (GPC-MALLS) was used to determine not only the extent of hydrolysis but also the concentration of oxidized functionalities within very low sample amounts (Henniges et al. 2016). An in-depth chemical and mathematical analysis of the aging processes for Hanji (traditionally used in Korea) is presented by Jeong et al. (2014). The aging of Hanji paper, resulting in hydrolysis and oxidation processes, was addressed using selective fluorescence labeling of oxidized groups in combination with GPC, providing profiles of carbonyl and carboxyl groups about the molar mass distribution.

Recent technical and scientific reports have shown that the main chemical reactions occurring in paper during aging were well identified using

noninvasive analytical spectroscopic techniques. The combination of several techniques could enhance historical paper analysis. On the other hand, since the multicomponent structure of paper complicates the analysis of ancient paper, a statistically relevant database of reference is required for data validation and practical use in further research. Moreover, conventional noninvasive analytical techniques require the data from a single point or a small portion of measured papers. Depending on the uniformity of the quality attribute within each historical paper, it might be necessary to repeat the data acquisition at several positions. This process takes a long time, even for low spatial resolution. A high-resolution and fast-speed method is expected to be useful for the evaluation of historical paper. Furthermore, sometimes artificially degraded papers were used for sampling instead of natural ancient ones; this has the advantage of sampling without using precious historical documents, and of improving the variance of experimental samples. However, the correspondence between artificially degraded papers through hydrolysis and oxidation processes and the natural aging process is still not clear, and needs to be proved in future studies.

Introduction

The first material support on which color was applied was skin, alive and dead. Traces of red ocher found on the bones of the Lady of Paviland (ca. 33,000 BCE), in southern England, signal the antiquity of the association between color, skin, and funerary rites. Similarly, in ancient Mesoamerican societies, skin, red color, and funerary rites have been associated since at least the Middle Pre-Classical period (ca. 1200–300 BCE). Through this practice, reddish body coloring materials, as a metaphor of the blood, were thought to confer life on the dead corpses following the symbolic logic of sympathetic magic, according to which “same begets same.”

Physical–chemical analyses and historical–cultural studies of these first body colors, and their successors in the Ancient World, have revealed connections between cosmetics, culture, and society, allowing those associations to be traced through antiquity. For this reason, the study of the preparation and use of cosmetics and perfumes in ancient societies has been the center of attention of various research groups at universities, research centers, and museums throughout the world. Since the 1990s, pioneering results have been obtained by research teams in France, Italy, and the United Kingdom principally. Success has largely resulted from the fact that these teams have optimized very precise physicochemical protocols based on the

combination of several analytical techniques (e.g., Walter et al. 1999; Gamberini et al. 2008; Van Elslande et al. 2008). These techniques include in actuality the use of light microscopy (LM), ultraviolet visible spectrophotometry (UV-vis), scanning electron microscopy electron dispersive spectroscopy X-ray (SEM-EDX), X-ray diffraction (XRD), X-ray fluorescence (XRF), Fourier transform infrared spectrometry (FTIR), voltammetry of microparticles (VMP), Raman spectroscopy (RMS), gas chromatography–mass spectrometry (GC-MS), and high-power liquid chromatography (HPLC). The combination of these techniques, capable of diagnosing mineral (SEM-EDX, XRD, or XRF), organic (GC-MS, HPLC), and hybrid organic–inorganic substances (VMP, RMS, FTIR), offers us the possibility to understand the technology of cosmetic and aromatic science in antiquity, and in consequence the link between materiality and cultural significances in ancient body colors and fragrances.

The methodology for the study of cosmetics and perfumes in antiquity required, as a consequence, interdisciplinary research teams composed of physicists, chemists, geologists, botanists, pharmacists, archaeologists, historians, historians of art, and anthropologists, in order to identify the preparation and use of these ancient cosmetics and perfumes in present communities.

For its part, written sources from ancient societies contain valuable information concerning additional ingredients that were probably incorporated into the cosmetic and perfume recipes used in antiquity, such as fragrances. These texts cite a number of such scented essences, which can help us to complete the formulation of archaeological scented cosmetics—very common in antiquity—and aromatic substances. These same written sources tell us that each one of these scents had specific uses, linked to specific ceremonies. Rose fragrances, for example, were recommended for banquets or *symposia* (Bourliascos 2004, 22), while the fragrance obtained from the saffron flower was required in ancient Aegean rites of passage, such as in the festival of the *Brauronias*, the ceremony of passage during which 12-year-old Greek girls ceased

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0447

to be *arkatoi* (girls) and became *osas* (women), according to historical writings such as *Lisistrata* by Aristofanes. The association between saffron, blood, the goddess Artemis, and the initiation of female fertility during this ceremony explains the symbolic and ritual meanings of saffron color and fragrance during the occasion (Vázquez de Ágredos 2011). In the New World, some chroniclers and dictionaries dating from the Colonial period describe fragrant flowers used by ancient Mesoamerican societies for different ceremonial purposes. Aromatic flowers used to prepare perfumes in antiquity were depicted in ancient art. Thus, the study of iconographic sources provides an important testimony with regard to this topic.

Cosmetics and perfumes in the Old World

In Ancient Egypt, many documents and objects, written texts, paintings, statues, artifacts, and toilet accessories support the fact that green and black make-ups were extensively used for their aesthetic, religious, and therapeutic properties. Cosmetics used to play an important role in everyday practices and during ritual and burial ceremonies. Make-up, named *ouadjou* when green and *mesdemet* when black, was part of a list of funeral offerings, including food, unguents, and oils, necessary to ensure the comfort of the dead person in the afterlife. Make-up containers were put inside the tomb to help the dead in the ceremonies involving purification in the afterlife.

The chemical study of 3,000- to 5,000-year-old cosmetics sampled from such containers made of stone, wood, or reed has shown that a restricted range of lead-based substances were used in developing a complex art of formulation (e.g., Walter et al. 1999). Three-quarters of the substances are lead-based compounds and are white, gray, or black. SEM and quantitative XRD have allowed us to identify four main phases: galena (PbS) for dark tones, and three white materials—cerussite (PbCO_3), phosgenite ($\text{Pb}_2\text{Cl}_2\text{CO}_3$), and laurionite (PbOHCl). It has been demonstrated that the last two minerals were synthesized, in particular from the lack of such compounds in and around Egypt, and this is

corroborated by a number of ancient texts from the Greco-Roman period. As these documents mention that these chemicals are good for eye and skin care, they were likely added to Egyptian make-up to confer therapeutic properties to the cosmetics. Today, the well-established toxicity of lead compounds has completely overshadowed their potential health benefits. New insights into the biochemical interactions between lead(II) ions and cells were obtained by electrochemical analysis of the biological interaction between cells from skin (keratinocytes) and submicromolar concentrations of Pb^{2+} ions in water (Tapsoda et al. 2010). Specific oxidative stress responses by the cells were observed, consisting essentially of the production of nitrogen monoxide (NO), which is known to play a role in stimulating nonspecific immunological defenses in tissues. One may then surmise that lead compounds with very low solubility (such as laurionite and phosgenite) were deliberately manufactured and used in ancient Egyptian formulations to prevent and treat eye illnesses by promoting the action of macrophages.

Concerning cosmetic typologies in use among the Phoenicians, little is known and generally references are from bibliographic Latin sources. In the Sicily museums (Palermo, Trapani, Marsala, Mozia) an important collection of Phoenician and Greek unguents showed white, black, blue, and red powders. XRD, FTIR, and RMS revealed two types of white samples: some mainly composed of gypsum and anhydrite and others of lead white (cerussite and/or hydrocerussite) and litharge. The second type of cosmetic corresponded to the most famous Greek make-up, called *psymition* in Greek and *cerussa* in Latin, used by women to whiten their faces. Lead white is a bright-white pigment with excellent coverage capabilities, because of both its high refractive index of light and its chemical synthesis technique that can, under certain conditions, produce the forming of very small grains with a platelet shape originating from the layered crystalline structure of hydrocerussite. The other materials suggested that, for the same use, alternative materials, cheaper and more readily available, could be employed.

The love of Phoenicians for the color red is evident from the great number of red powders, used on cheeks and lips: hematite, cinnabar, red lead, and the very rare lead chromate. The

materials' heterogeneity used for make-up, even, for example, in comparison to the Roman culture, revealed a palette less extensive and less refined. Classical sources such as Pliny and Ovid report exotic and sophisticated ingredients for Roman cosmetics. Instead, analysis of Pompeian cosmetic powders suggest a more economic and simple daily *cosmesis*. The numerous black powders were mostly made of carbon (soot) and used for eye and eyebrow outlining. Certainly, soot was an economic and available alternative to more expensive Egyptian *kohl* or less common *stimmi*, synthesized by heating lead and sulfur, not found in Pompeian powders. The white powder contained principally calcite and gypsum, and sometimes cerussite and aragonite (white shell). Calcite was described as a foundation, and it is more common than lead carbonate (*cerussa*), rare in analyzed samples from the Roman period, but often mentioned in the literature. The pink make-up was a mixture of several products, often hematite (ocher) lightened with a white pigment (often calcite). Only in one case, surface-enhanced Raman spectroscopy (SERS) use permitted identification of a plant from the Rubiaceae family used to color the clay instead of the expensive *purpurissum*: Pliny speaks of "purple of Pozzuoli" gotten with *Rubia tinctorum*. Finally, analysis of these Roman cosmetics from Pompeii and results obtained in Gaul and Germany have shown the use of materials more commonly found in nature (Welcomme et al. 2006). Black powders, usually used to outline the eyes, were mostly prepared with simple carbon (vegetable or animal). A blue powder consisted of the famous Egyptian blue.

Body colors and fragrances in the New World: Mesoamerica

In accordance with the first physicochemical results obtained in recent years, in ancient Mesoamerica the coloring materials used to prepare body colors were calcite (CaCO_3), clays, gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), and diatoms (*Bacillariophyta*) (white); charcoal, galena (PbS), and manganese oxide (MnO) (black); jarosite ($\text{KFe}_2(\text{SO}_4)_2(\text{OH})_6$), limonite ($\text{Fe}_2\text{O}_3 \cdot n\text{H}_2\text{O}$), goethite (FeOOH), and hematite (Fe_2O_3)

(yellow); and red earths (varieties of hydrated iron oxide), hematite, specular hematite (Fe_2O_3), ilmenite (FeTiO_3), and cinnabar (HgS) (red and orange). Written and iconographic sources also describe the use of blue body colors by ancient Mesoamerican societies, probably prepared with indigo (different species of *Indigofera*, such as *Indigofera suffruticosa*, *Indigofera mucrolata*, and *Indigofera jamaicensis*), which still have not been identified by physicochemical analyses.

On some occasions, these body colors presented a simple formulation, composed of only one element: the chromatic pigment-matter itself. However, it is more common to identify mixtures composed of two to five components. It is in these composite cases that we can properly determine their intended formulations and technical recipes. In body colors discovered in the neighborhood center of Teopancazco (Teotihuacan), for example, the three most recurrent components in those formulations were the pigment itself, an organic additive, and mica. These constituent components were found in combinations of two constituents (pigment₁-pigment₂; pigment-mica; pigment-organic additive) or combinations of all three constituents (pigment-organic additive-mica; pigment₁-pigment₂-mica; pigment₁-pigment₂-organic additive; pigment-organic additive₁-organic additive₂) (Vázquez de Agredos, Pascual, and Manzanilla 2016). A fourth component, clay, was regularly encountered, albeit less often. We believe that at Teotihuacan the purpose of many of these formulations was to create body pigments which not only served to paint the body but also conferred hygienic/medicinal properties on the skin. In fact, those combinations contributed to these cosmetics three qualities: brightness, aroma, and medicinal properties. Some body colors, such as cinnabar and galena, and mica (biotite-type mica) contributed the brightness. Choosing biotite-type mica enabled producers to recreate yellow and red cosmetics that were "dotted" with a translucent orangey-amber or reddish glitter, which is the chromatic effect given off by biotite. On the other hand, a lot of body colors from Teotihuacan contain an aromatic organic additive, normally pine resin (*Pinus montezumae*), chia oil (*Salvia hispanica* L.), or a mixture of both. Technically, a resin is insoluble in water; this means that in order

to agglutinate color that can spread on the skin, an alkaline solution or oil is required. Oil applied to the body colors a medium texture that was different from the plaster obtained by mixing only pine resin with the cosmetic; it was also different from the oily fluidity of some body colors in which only chia oil was identified. This combination likely produced three different textures with different viscosities. Each formulation also provided its own scent to the body pigment. Lastly, we should not forget the strong rituality that impregnated each of these aromas; pine resin, for example, plays an important role in the religious beliefs and daily lives of ancient Mesoamerican societies, which also documented the presence of body colors mixed with this type of fragrance substance. In the case of ancient Mayas, such products were found as traces of pigments introduced in royal tombs in Mesoamerica as funerary offerings, or otherwise used to embalm the interred dynastic corpses. Preliminary results collected in recent years—which, incidentally, are the first results to be obtained after more than a century of archaeological activity in Mesoamerica—suggest that they are perfumed ointments with cosmetic properties. In other words, they are body unguents or lotions comprising color and aroma. In this sense, we have identified triterphenic compounds typical of bursera-type resins, such as copal (*Bursera copalifera* L.), used to agglutinate and aromatize cinnabar-based (HgS) body pigment, which was used to embalm the Red Queen of Palenque, a high Maya dignitary and possible consort of King K'inich J'anaab Pakal (603–683 CE; Late Classic) (Vázquez de Ágredos et al. 2015). Cinnabar thus treated was likely destined to slow down postmortem degradation and putrefaction of royal corpses, given that the mercury contained in its composition confers this retarding effect. This interpretation seems even more reasonable because, in accordance with inscriptions found in royal tombs, the ritual preparation of the deceased bodies could last for up to ten days, long enough to risk unpleasant odors and decomposition stench during the public funerary pomp, especially in the jungle of the Maya Lowlands. Likewise, we have recently identified diterphenic compounds used with red body pigment produced by iron oxide (Fe_2O_3) and mercury sulfur (HgS), which were found

in a funerary chamber inside Lundell Palace in Calakmul (Early Classic).

Thus, the first physicochemical results obtained on ancient cosmetics used in Mesoamerican societies described body colors prepared with the same coloring materials employed in other societies from the Old World (calcite, galena, jarosita, and hematite, among others), with the exception of blue and green cosmetics. These body colors were used in daily life, in accordance with writing and iconographic sources, but also in funerary contexts as offerings or on shrouds. Frequently these body colors or cosmetics were mixed with organic substances with aromatic properties, and/or in some formulations with luminous materials, such as mica.

Epilogue: the versatility of uses of ancient cosmetics and perfumes

The magical/ritual and medicinal properties of most pigments and aromas used to prepare cosmetics and perfumes in ancient societies from the Old World (Sumer, Egypt, Greece, Etruria, and Rome) and New World (Mayas, Teotihuacans, Zapotecs, Tarascos, Mixtecs, and Aztecs) explain how their physicochemical identification has allowed a better understanding of the cultural and functional aspects of these corporal pigments of malleable texture and pleasant fragrance. In other words, the study of cosmetics and perfumes opens the door to study color, aroma, drugs, and magic in antiquity and their connection with religious practices that cohered human groups and gave them a sociocultural identity.

This is the case, for instance, in medicine, where a raw material such as hematite (Fe_2O_3) and galena (PbS) was used in ancient Egypt since pre-dynastic times, not only as a pigment and/or cosmetic but also to treat illnesses and manufacture amulets. This coloring material was used as a cosmetic and medicinal substance by the Aztecs in Post-Classic times, as described by Martin de la Cruz in *Libellus de Medicinalibus Indorum Herbis*. In the same way, in ancient China, cinnabar (HgS) was used as a pigment, drug, and important alchemical ingredient. Finally, the use of diatomaceous earth in medicine and cosmetics dates back to ancient Mesopotamia. It

was used because of its antiseptic, antibacterial, and fungicidal properties, which act upon the skin as a barrier against germs, bacteria, and fungi, just as do algae (Kumar et al. 2013). These and other properties, like the antioxidants and anticoagulants that some species contain, were known and applied for medicinal use in ancient Near-Eastern and North African societies. The medicinal properties of diatomaceous earth are further attested in ancient populations of Central Mexico, in accordance with prescriptions from *Libellus de Medicinalibus Indorum Herbis*.

Petrography and Ceramics

CHANDRA L. REEDY
University of Delaware, USA

History of petrography and ceramics

Petrography has a long history as a method for studying ceramic materials, and was developed in geology even earlier. It is used to investigate raw material sources, fabrication methods, functions, exchange networks, technological styles, use histories, and deterioration products. A small sample is cut from a ceramic shard, attached to a microscope slide with an epoxy resin, and ground to 30 μm thickness. At this standard thickness, minerals show a variety of optical properties that can be used to identify them under a polarizing transmitted light microscope. Both plane polarized light and crossed polarized light are used, as each provides information on different mineral properties. While clay minerals themselves, because of their very small size, cannot be discerned in thin sections, larger additives and minerals co-occurring with the clay can be identified. In addition to mineral identification, thin sections reveal information about porosity characteristics, decorative layers, and textures such as the amount, size, shape, and distribution within the matrix of larger particles that occur naturally in clay deposits or that were added by the potter to improve working, drying, firing, or the use properties of the clay.

This technique was used for answering archaeological questions regarding ceramics as far back as the early 1940s. For example, at early excavations of ancient Troy, petrography was successful at distinguishing local from imported wares, examining chronological differences among ceramics, identifying fabrication methods, and deducing the degree of control over firing. Over the following 75 years, major advances have been made by ceramic petrographers working all over the world, on many types of ceramic materials

and in the service of a wide range of research questions (Reedy 2008; Quinn 2013; Ownby, Druc, and Masucci 2017).

Characterization of inclusions for grouping, provenance, and exchange network studies

Many successful characterization studies addressing archaeological questions about workshop groups, provenance, and the extent of trade and exchange networks have focused on thin-section analysis of the nonplastic inclusions found in ceramics (Figure 1a). These inclusions can occur naturally in clay deposits or can be deliberate additions (often called “temper”) of the potter. Such inclusions improve the working, drying, and firing properties of clay and can impact the use properties of ceramic materials. Typical inclusions are rock fragments, grog (ground ceramic fragments), organic matter, sand, and other materials. Identifying the type of inclusions present and the size, shape, distribution, and abundance of each type of inclusion can be helpful in characterizing, grouping, or comparing ceramics and determining possible sources of raw materials.

In addition to identifying what inclusions are present, it is also often useful to calculate the area percentage of a shard occupied by inclusions (as a measure of the volume percentage chosen by the potter); the relative amount of each grain type; and minimum, maximum, and average grain size or shape. Methods to obtain these data can include visual estimation aided by published visual estimation charts, taking measurements with a microscope eyepiece graticule, point counting, and digital image analysis. Beyond focusing on the inclusions in isolation, Ian Whitbread (1995) pioneered the application of descriptive and statistical techniques from sedimentary petrography and soil micromorphology to characterize and group ceramic fabrics, and has successfully used that approach to answer a number of archaeological research questions in the Aegean.

Figure 1 (a) A thin section (crossed polarized light) of a low-fired ceramic shows large, angular granitic inclusions, most likely from a crushed rock additive (temper). Many smaller quartz and feldspar grains appear within the clay matrix. Some may be natural inclusions in the clay, others may have flaked off of the granitic temper. (b) In a high-fired ceramic (plane polarized light) the original minerals that were present have been transformed into new high-temperature phases. Two large, clear, rounded pools of silica glass formed where quartz melted; the one in the center is partially covered by minute tile-shaped grains of cristobalite. Tiny mullite needles fill the glassy matrix where all feldspars have melted.

Petrographic studies involving the identification of rock fragments in ceramics have revealed a wide range of rock types such as obsidian, tuff, pumice, basalt, andesite, sandstone, limestone, dolomite, chert, mudstone, granite, phyllite, schist, marble, quartzite, and many others (Reedy 2008; Quinn 2013). One example of the many successful ceramic petrography studies that have focused on the analysis of rock fragments is Maggetti (2005). In that case, the question of interest was the extent to which the Alps served either as a barrier to or as a passage for ceramic trade in prehistory. A total of 454 shards from ceramics from the Laugen–Melaun (Luco–Meluno) culture in northern Italy, eastern Switzerland and Liechtenstein, and western Austria were examined in thin section. Many of the ceramics from northern Italy contained volcanic rock inclusions (rhyolite) that could be traced to rocks from that region, so they clearly represent local or regional ceramic production. Many ceramics containing the same rhyolite inclusions were also found in southeastern Switzerland, which lacks local sources of rhyolite; the find indicates that trade in ceramics occurred along

that route. However, the percentage of imported versus local wares decreased significantly over time (from 70% in the eleventh century BC to 10% by the sixth century BC); and no imported rhyolite pottery was found north of the Alpine crest in Switzerland, in Liechtenstein, or in Austria (serpentine rock fragments were found in those ceramics instead). This study illustrates the fact that rock fragments found in ceramic materials can often be traced to specific geological sources, so they are often useful in provenance studies that can illuminate archaeological questions about local production versus long-distance trade and exchange.

A “grog” temper refers to the addition of crushed fragments of previously fired ceramic pieces. These often come from shards of broken pottery. If the shards used as a source of grog derive from the same clay as the ceramic objects they are tempering, this is an advantageous additive, because there will be a close match in physical properties. Grog can be a good additive for clay with few natural mineral inclusions and needing some temper to improve drying and firing performance. However, grog is often just

one of a mix of tempering additives used. Grog can be difficult to identify with certainty in thin section, because it may look quite similar to argillaceous rock fragments derived from sedimentary material such as lithified clay, mud, or silt. The presence of a slip or glaze retained from the original shard can, however, securely identify the presence of grog.

As a variation on grog, sometimes small balls of clay were dried, fired, and then used as a deliberately manufactured temper material. Potters may choose this approach if there are no natural sources of potential additives (such as sand or rock deposits) close at hand. Sometimes the preference for manufactured temper is found even where other, natural additives are available. For example, Vincent (1988) found that manufactured grog was used in northeastern Thailand on the Korat plateau to control the shrinkage qualities of the local clays. The sedimentary rocks available on the plateau have a wide range of expansion rates; so, where clay quality is marginal, adding a lithic temper could be problematic. Control over the physical properties made the additional investment in time and fuel required to prepare the artificial temper worthwhile.

Sand, a common natural component of clay deposits and a frequent potter's additive, is comprised mainly of quartz. Frequently, quartz-rich sands from different locations appear at first glance to be so similar that they may be considered undiagnosable. However, by combining geological maps, field collection of sands, and appropriate statistical techniques, the petrographic analysis of sand in ceramics becomes more useful for archaeological studies. In a groundbreaking study of sand additives in ancient ceramics from central and southern Arizona, geological maps were used to construct preliminary diagrams of distinct sand composition zones along a river system, and then sand samples were collected from streams in that system (Heidke and Miksa 2000). Quantitative data on quartz amount, size, and shape from the sampled sands were used for statistical analyses to refine the original diagrams and to derive a mathematical function to best discriminate between sand locations. This discriminant function was then used with ceramic thin sections, to identify the most likely location where potters collected their sand. Ceramic production and

distribution patterns could be identified. In addition to the analysis of the quartz content of sand, sand tempers can often be characterized using other common constituents of sands such as feldspars, iron oxides, calcium carbonates, micas, and organic material. Sand-tempered ceramics can vary greatly in the presence, size, amount, or relative proportion of these different components.

Organic materials often serve the function of a temper additive in ceramics. If pottery is fired under reducing conditions, this material often remains charred in places and may be identifiable. Agricultural waste, such as the straw or stems from crop plants, may be seen. Other organic materials that have been identified in thin sections of ceramics include seeds or husks, animal dung, phytoliths, animal hair, feathers, textile fragments, and moss fibers. If the pottery was fired in oxidizing conditions, most or all of the organic matter may burn out during firing. Large pores may remain; these can be advantageous for various uses, such as in cooking pots or water storage vessels. Often some carbon residues may be seen along the edges of these pores, offering evidence that organic material was originally present. Quantitative pore analysis may help identify the amount of temper used, and the pore shapes can give clues as to what type of organic matter may have been used.

In low-fired ceramics, the nonclay minerals originally present as natural or added components remain unchanged or only slightly altered after firing. In this case, combining the use of geological maps with field surveys and the collection of comparative raw materials has emerged as an extremely useful approach to thin-section petrography that aims to identify specific sources of raw materials (Ownby, Druc, and Masucci 2017). This procedure takes full advantage of the geological roots of thin-section petrography and of the range and type of information viewable in thin sections. While early studies mainly focused on identifying the geological sources of rock-fragment additives, there are now many studies involving the characterization of clay deposits, with their natural impurities of larger nonclay particles.

Petrography and characterization of ceramic production methods for technological studies

While many petrographic studies of ceramics focus on the characterization of nonplastic particles (whether natural inclusions or deliberate additions) and on identifying geological sources of raw materials in order to answer questions related to workshop locations and trade and exchange connections, there are many other research questions that can be investigated through thin-section petrography. Foremost among these are questions related to the *chaîne opératoire*. Thin-section petrography can reveal information about clay selection and processing choices, object fabrication methods, firing conditions, and decorative techniques.

Clues as to clay preparation methods may be found in thin-section studies of the appearance of the clay matrix and of the distribution of coarser nonplastic components that are often present in clay deposits. For example, a clay paste with a very homogeneous appearance in grain size, content, and distribution may indicate that considerable effort was expended in clay-processing steps. By contrast, if little effort was spent on grinding, sieving, and mixing the clay, thin sections may show lumps of unevenly colored clay distributed here and there within a matrix of uneven distribution of the nonplastic particles. Wedging and kneading steps can eliminate many of the larger air bubbles within the clay matrix and produce a relatively uniform distribution of fine air bubbles. Thin sections that show many voids of varying sizes may be an indication that little wedging and kneading were done; whereas voids of relatively small and uniform size and distribution may indicate more thorough processing and preparation of the clay (Reedy 2008; Quinn 2013).

In one example, Velde and Druc (1999) used thin-section petrography to contrast the paste preparation methods of fine-grained *sigillata* ware and coarse-grained Neolithic wares in central France. The homogeneous mix of clays and small temper grains in the *sigillata* ware, with even distribution of fine grains and an even texture, indicated that careful steps in the preparation of

the paste included crushing, sieving, and impurity extraction. Thin sections of the Neolithic wares, by contrast, showed a very irregular distribution of grain sizes; there was also a “zoning” effect created by patches of fine grains interspersed with areas of larger grains. In this case, the paste was made from an inhomogeneous clay, which was not homogenized after extraction; it did not appear to have been ground, sieved, or mixed.

Ceramic-forming and fabrication methods can also be investigated through thin-section petrography in conjunction with a study of shards and whole vessels, and often with input from ethnographic work and replication studies. Thin-section analysis may reveal clues not visible through surface examination alone. For example, the orientation and alignment of platy particles such as micas or other elongated inclusions, and of voids or pores, can help differentiate forming methods such as use of a wheel, coiling, paddle and anvil, or building in segments (Middleton and Freestone 1991; Gibson and Woods 1997; Velde and Druc 1999; Reedy 2008; Quinn 2013).

While thin-section analysis of low-fired ceramics can help identify the geological source of the mineral and rock inclusions, with high-fired ceramics the original minerals are transformed into new, high-temperature minerals (Figure 1b). This is the case with many Asian ceramics, for example, which are often stonewares or porcelains. In this case, thin-section examination of minerals in ceramic bodies and glazes can provide information about firing and cooling regimes. For example, quartz grains that undergo significant thermal shock from rapid heat rise can crack. If held in the kiln for long enough at high temperatures ($\geq 1250^{\circ}\text{C}$), quartz can convert to cristobalite, which in thin section looks like very small tiles forming over the quartz grain; if even higher temperatures are reached, silica glass can also form (in thin section these look like clear, round pools). A high-temperature mineral often seen in Chinese glazes at $\geq 1000^{\circ}\text{C}$ is anorthite, a calcium aluminum silicate mineral that frequently forms as an interaction product at the boundary between clay and a lime-rich glaze. However, fully understanding firing and cooling conditions is complicated, because the final appearance is the result of many variables, including mix of raw materials, maximum temperature attained, rate of temperature rise, rate of

cooling, total duration of firing, time maintained at peak temperature, and atmospheric conditions during firing (oxidizing, reducing, or a combination). Typically, thin-section petrography is one tool among many that are called upon in a study of ceramic firing and cooling regimes.

Thin sections provide a good view of decorative layers on a ceramic. Subtle evidence of burnishing or polishing to produce a more lustrous surface may be more visible in thin section than to the unaided eye. Fine particles, especially the platy clay and mica minerals, may show a clear parallel orientation that is due to surface burnishing, versus a more random orientation at greater depth into the ceramic material. Applied decorative layers can include slip, paint, glaze, or enamel layers. Petrographic thin sections can help identify the presence of a deliberately applied layer and the order in which multiple layers were applied. The thickness of layers can be measured (the average, and the minimum and maximum), which can provide clues as to similarities and differences in decorative technology among workshops.

Thin-section petrography is also helpful for studying the presence, distribution, and characteristics of interaction layers that may form as the clay body encounters a decorative layer. For example, the clay matrix often begins to melt at a body–glaze boundary region, forming new secondary minerals. In many Chinese and other Asian ceramics, a lime-rich glaze interacts with melting clay at the boundary area to form thin needles of anorthite. This layer of anorthite creates a white ground under the glaze, reflecting light back through the glaze and contributing to a lustrous quality. Bubbles created as gases are released by ceramic bodies and glazes at high temperatures often become trapped within the glaze. These, too, contribute to the reflective quality of many Asian glazes. Potters often deliberately determine the temperature, firing duration, and glaze viscosity in order to control the amount and size of bubbles so as to produce the specific surface effects desired. Thin-section petrography can clarify the range and variability of bubble sizes and their locations in the glaze layer, providing additional clues about the firing and glaze technology and the aesthetic intent of potters and kiln managers.

New directions and the continued power of petrography in ceramic analysis

Petrographic ceramic analysis is still a very active field of research. Some current work extends the methodology itself, for instance by adding high-resolution geological scanners and image analysis (Reedy 2008). Other work extends the type of materials characterized (e.g., volcanic ash temper, loess, microfossils, etc.) and the range of archeological and anthropological questions that are tackled (Quinn 2013; Ownby, Druc, and Masucci 2017). Often petrography, with its unique capabilities, is combined with other analytical methods to extract the maximum amount of information possible from a study of ceramic materials. By using all available tools, ceramic petrographers help resolve some of the fundamental questions in anthropology and archaeology.

Pigments and Binders

MARIA PERLA COLOMBINI and ILARIA DEGANO

University of Pisa, Italy

Pigments and binders have been used since prehistory to paint colored layers. Over the centuries, artists started to develop specific recipes to improve their performance, in terms of both the aesthetic appearance and durability of their paintings.

Painters experimented with a multitude of materials as paint vehicles. Organic binders typically adhered to the ground layer and also provided a matrix capable of suspending the pigments. Specific binders were needed to form stable films with aesthetic properties, and can be divided into two main classes: inorganic and organic. The most famous inorganic binder is calcium carbonate, used in the *fresco* technique; however, lime techniques also fall within the category of paints achieved with inorganic binding media. Natural organic binders include proteinaceous, glycerolipid, and saccharide materials. Synthetic and semisynthetic organic binders are also widespread, as will be detailed in the following sections.

Frescoes

In frescoes, the binder is the product of a chemical process, resulting in a mechanical bonding of the pigment particles, as follows:

- The plaster is a water mixture of slaked lime and an aggregate ($\text{CaO} + \text{H}_2\text{O} \rightarrow \text{Ca(OH)}_2$).
- The plaster dries and acts as a ground layer, support, and binding agent, locking the pigment particles into place through the formation of calcium carbonate ($\text{Ca(OH)}_2 + \text{CO}_2 \rightarrow \text{CaCO}_3 + \text{H}_2\text{O}$).

Due to the high alkalinity of the substrate constituted by fresh plaster, only stable inorganic

pigments (such as green and red earths, Egyptian blue, San Giovanni white, hematite, goethite, lapis lazuli, ivory, and carbon black) dispersed in water are used in frescoes. Neither lakes nor organic pigments can be used in this technique due to the strongly alkaline conditions.

Proteinaceous paint binders

Proteinaceous paint binders, mainly egg, casein, or animal glue used as tempera, are polymeric materials made up of a specific sequence of amino acids dispersed in water and containing a small amount of lipids. Once applied onto the substrate with the pigments, the water contained in the raw material evaporates, leaving the polymeric structure to form the paint film. Protein-based binders are some of the most commonly used and the most durable (Colombini 2009, 237–259). Other proteinaceous binders were used in the West, such as garlic in gildings (Colombini 2009, 4–6, 237–239).

Glycerolipid binders

Binders for oil paints are generally prepared using siccative oils, such as linseed, walnut, or poppy seed oils in western countries and tung oil in the East. These oils are characterized by their high triglyceride content containing highly unsaturated acyl chains, for example, trilinolein in linseed oil. The pigments are dispersed in the medium, which, once applied on the substrate, starts to polymerize thanks to the action of light and atmospheric oxygen. Oxidation and polymerization reactions occur to form the paint film, as a result of the subsequent radical reactions (Colombini 2009, 191–213).

Oil binders have also been applied in mixtures with proteinaceous materials (generally egg) to obtain the so-called *tempera grassa*. This technique was used in the Renaissance and was rediscovered in the twentieth century. Technical

issues and the use of tempera were keenly debated among those artists involved in the renewal of the classicist style and traditional working methods. Consequently, numerous formulations containing proteinaceous binders were developed. Today, the term “tempera” is more related to the rheological properties of the paint, which are strongly influenced by minor additives (such as glycerol, soaps, or tallow) more than the main constituents (proteins and/or lipids).

Other lipid-based paint binders include natural waxes. Of these, beeswax was the most common, particularly to produce Punic wax (thought to have been the main ingredient in *encausto* paint). Waxes are hydrophobic substances made up of complex molecular mixtures containing various homologous compounds such as fatty acids, *n*-alkanes, *n*-alcohols, and esters in varying percentages depending on the origin of the material (Colombini 2009, 97–100).

Polysaccharide binders

The most common polysaccharide paint binders are natural gums. Plant gums are naturally occurring polysaccharide exudates from several species of plants or extracted from the endosperm of some seeds. The polymers consist of aldopentoses, aldohexoses, and uronic acids joined together by glycosidic bonds. Saccharide paint binders were used for several purposes, and watercolor painting, involving the use of Arabic gum, is one of the most famous (Bonaduce et al. 2016). However, saccharides have been found as paint materials in several archaeological contexts. As a painting material, this binder is one of the most labile, as it is subject to biodeterioration.

East Asian Asian lacquers

Lacquers are natural polymers that have been used as both varnishes and painting media since ancient times and consist of the sap extracted from trees growing in East Asia and Japan. Chinese, Korean, and Japanese lacquer trees (*Rhus verniciflua*) all contain urushiol as the monomeric unit, while Taiwanese and Vietnamese lacquer

trees (*Rhus succedanea*) contain laccol, and *Melanorrhoea usitata*. Thai and Burmese lacquer trees contain thitsiol. Minor components have been found in the polymeric structure of the lacquer, whose properties also depend on the recipe used for its production.

Semisynthetic paint binders

Natural binders were modified greatly over the course of the nineteenth century to meet the need for stable and fast-drying artist materials. The introduction of paint tubes forced manufacturers to use additives to improve the durability of their products. “Modern oils” were thus introduced, which contained not only siccativ but also semisiccativ and nonsiccativ oils (safflower, sunflower, palm, and castor oils). The tubes contained inorganic species (CaCO_3 , MgSO_4) to improve the texture, surfactants such as metal soaps, and pigments. Since the 1940s, natural oils have been modified to obtain alkyd paints/resins, which are oil-modified polyester paints prepared from natural oils and treated to improve their polymerization, by adding a polyol (trimethylolpropane, glycerine, or pentaerythritol) and dicarboxylic acids or anhydrides, such as phthalic anhydride or maleic anhydride. They are typically sold in tubes with the addition of pigments and several species to improve texture and durability (van den Berg 2014).

Synthetic binders

One simple way to describe synthetic binders is to classify them into two main groups: artists’ paints (mainly acrylic and oil), and house paints (usually alkyd and polyvinyl acetate) (Learner et al. 2008). The first, introduced in the late 1920s, was nitrocellulose house paint, followed by alkyd house paint in the 1930s, and polyvinylacetate (PVA) emulsion house paint in the 1940s. Artists’ acrylic solution paint followed in the late 1940s and acrylic emulsions in the mid-1950s.

The house paint polyvinyl acetate (PVA) entered the market at the same time as alkyd

paints, and was slightly modified by adding a plasticizer or copolymerization with a softer monomer to improve its performance.

Pigments

Pigments fall into two main categories: inorganic and organic. A pigment is a species that absorbs visible light. This is due to either the transition elements, found in inorganic pigments, or the delocalization of the electrons in conjugated unsaturated systems in organic pigments. Given that pigments are insoluble in the medium, organic pigments are often obtained by complexation or adsorption on an inorganic, uncolored salt. Organic pigments obtained by complexation or adsorption are generally called pigment lakes. If the organic species is insoluble in the medium, or, being strongly acid or alkaline, is precipitated as a salt, it can be referred to as an organic pigment. Some examples of the most commonly used pigments are listed in Table 1.

In the past, the pigments available to artists were very limited, and some, such as ultramarine blue, were so expensive that they were only used for precious decorations. Manufacturers of artists' paints currently produce a very large variety of pigments in paint tubes, mainly of an organic nature. These modern pigments have a uniform particle size, are compatible with oil or synthetic binders, and are reasonably resistant to environmental conditions.

Characterization of pigments and binders

Characterizing the pigments and the binding media in a work of art is challenging for chemists and physicists. The most common techniques for inorganic species are those based on elemental analysis, in particular X-ray fluorescence (XRF), and electronic spectroscopy, such as fiber optic reflectance spectroscopy. These techniques can be used both nondestructively and noninvasively on the painting. Another common technique is scanning electron microscopy energy dispersive X-ray analysis (SEM-EDX) applied on samples in thin and cross-sections. To provide more detailed information on the molecular structure

of the pigments, Fourier transform infrared spectroscopy (FTIR) or Raman spectroscopy are the most common techniques.

FTIR and Raman spectroscopy can provide information on organic pigments and binders, but being bulk methods, both techniques suffer from matrix effects. More extensive information can only be obtained by applying microdestructive techniques, such as chromatography and mass spectrometry (MS). The separating power of liquid chromatography (LC) and gas chromatography (GC), coupled with the specificity and sensitivity of MS detection, often lead to the unambiguous identification of the binding medium, even in extremely aged and degraded samples, and of organic pigments (Colombini et al. 2010; Bonaduce et al. 2016; Degano and La Nasa 2016). The application of proteomics is a particular example, which may lead to binder identification when ambiguous characterizations are obtained with GC/MS techniques.

Finally, to establish the spatial distribution of the organic and inorganic materials identified, synchrotron radiation FTIR (SR micro-FTIR) and SR XRF and X-ray diffraction (XRD) can be used to collect high-contrast chemical images which are fundamental in defining the painting technique (Bertrand, Dillmann, and Reiche 2015).

Determining both pigments and binders leads to a comprehensive characterization of the painting from a chemical point of view. Good examples of comprehensive examination of the constituting materials include the study of western painting techniques and the characterization of the organic media in the wall paintings of the "Palace of Nestor" at Pylos, Greece, which show evidence of a *secco* painting technique in the Bronze Age (Brecoulaki et al. 2012). In addition, in eastern countries, the determination of the organic materials in the Five Northern Provinces' Assembly Hall revealed the technique of the Qing dynasty painters in civil buildings (Lluveras-Tenorio et al. 2015).

Table 1 Examples of the most commonly used pigments.

<i>Name of pigment</i>	<i>Color</i>	<i>Formula/chemical class</i>	<i>Notes</i>
Lead white	White	$2\text{PbCO}_3 \cdot \text{Pb}(\text{OH})_2$	Most commonly used white until the nineteenth century
Lime white (San Giovanni white)	White	CaCO_3	Mostly in wall paintings
Titanium dioxide	White	TiO_2	Synthetic (1920)
Gypsum	White	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	Mostly used for ground layers
Azurite	Blue	$2\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$	Very precious
Ultramarine blue (lazurite)	Blue	$(\text{Mg}, \text{Fe}^{2+})\text{Al}_2(\text{PO}_4)_2(\text{OH})_2$	
Smalt (cobalt glass)	Blue	Obtained by including cobalt oxides in a glass melt and grinding the final product	Mostly used in the seventeenth–eighteenth centuries
Indigo	Blue	Organic, natural	Used in America
Maya blue	Blue	Indigo adsorbed on clay	
Malachite	Green	$\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$	Synthesized by Greek and Roman painters
Verdigris (copper acetate)	Green	$\text{Cu}(\text{CH}_3\text{COO})_2 \cdot 2\text{Cu}(\text{OH})_2$	
Phthalo green	Green	Copper phthalocyanine	
Yellow and red ocher	Yellow-red	Fe_2O_3 (from yellow to red depending on the hydration)	Very stable, synthetic (1936)
Lead chromate	Yellow	PbCrO_4	
Red lead (minium)	Red	Pb_3O_4	Commercially available since 1818
Vermilion/cinnabar	Red	HgS	
Madder lake	Red	Vegetal anthraquinones precipitated as a complex with alum	Lake from ancient times
Carmine	Red	Animal anthraquinones (carminic acid mainly) precipitated as a salt	Very precious, seventeenth century
Eosin	Pink-fuchsia	Organic pigment (xanthene class)	Synthetic, very fugitive
Ivory black	Black	Amorphous carbon obtained from ivory and animal bones, also containing calcium phosphate and carbonate	
Carbon black/vine black	Black	Amorphous carbon obtained from organic material	

Liquid Chromatography (HPLC); Infrared Absorption Spectroscopy (IR, FTIR, DRIFT, ATR); Mass Spectrometry (MS); Polymers in Conservation; Raman Spectroscopy and Material Analysis

PIXE and Material Analysis

JOSE LUIS RUVALCABA-SIL

Universidad Nacional Autónoma de México, Mexico

Material analysis for archaeology

Archaeological objects and materials are a primary source of knowledge about the societies of the past, the exploitation of sources of raw materials, the technology and manufacturing techniques of objects, exchange routes and trade, chronological data, and deterioration. For this reason, it is very important to apply a suitable set and sequence of techniques for characterization of materials. Imaging techniques provide a global examination of objects at macro- and microscopic levels to select specific areas for non-invasive methods, such as spectroscopic techniques for in-situ and laboratory analyses (X-ray fluorescence, Raman and Fourier transform infrared spectroscopies, ion beam analysis). After these analyses, and depending on the archaeological questions and the kind of material studied, sampling may be considered for microanalysis using methods of optical and electron microscopy techniques, spectroscopies and chromatographies.

From the 1990s and during the first decade of the 2000s, there was a rapid development of ion beam analytical methods for heritage and archaeology. Several methods were improved, new instrumentation was developed, and specialized laboratories and groups were implemented worldwide. In particular, particle induced X-ray emission spectroscopy (PIXE) and Rutherford backscattering spectrometry (RBS), complemented by particle induced gamma-ray emission spectroscopy (PIGE), provide a unique analytical tool when an ion beam accelerator is available. Often, the combined use of elemental analysis with other techniques is necessary for a complete and correct interpretation of the data. PIXE can be successfully applied to practically all kinds of

inorganic materials and objects from the archaeological record: pottery, stone objects (obsidian, flints, jade), gems, metallic artifacts, glaze, glass, bone and teeth, manuscripts and paintings.

PIXE and other ion beam methods

PIXE is based on the interaction between a monoenergetic positive ion beam, mainly hydrogen (proton) or helium (alpha particle) ions, and the electrons of the atoms of materials. These ions have enough energy to cross the electronic clouds and to eject electrons from the inner electronic shells. Atoms are ionized, and to recover their natural energy state, electrons from outer shells undergo transitions in order to fill the holes left by the ejected electrons in the inner shells. These transitions are accompanied by emission of energy, as X-rays, with specific energies that correspond to the energy gap between the electron shells (see Figure 1). The energies and intensities of emitted X-rays are characteristic of the chemical elements and the elemental concentrations in the material.

Certain electron transitions will emit energy in the range of ultraviolet to infrared light. This light emission is characteristic of the material and its elemental impurities. The technique that captures this effect is called ion beam induced luminescence (IBIL) or ionoluminescence (IOL).

Other secondary emissions are simultaneously produced by Coulombian repulsion between the nucleus and positive ions: the ion beam can be scattered, and the change in the energy of the scattered ions is specific for each kind of atom. This is the physical principle of Rutherford backscattering spectrometry (RBS), which is useful for measuring the composition of the light elements and the elemental depth profile.

If the ion beam energy is high enough to overcome the nuclear repulsion, the ions can reach the nucleus and reactions take place, emitting particles and gamma rays of characteristic energies that are specific for each atom. This effect

Figure 1 Ion beam interaction with the atom to induce characteristic X-ray emissions.

is more likely for light elements (such as fluorine and sodium), and it is the principle of particle induced gamma-ray emission spectroscopy (PIGE).

Since all these phenomena occur simultaneously, modern ion beam analysis involves the detection of all the secondary emissions (Beck et al. 2011). Characteristic X-ray emission is the most probable phenomenon, and for this reason PIXE is the most used and versatile ion beam technique.

Experimental setup and analytical capabilities

For archaeological applications, external beams are the most appropriate systems because it is possible to analyze the object directly in a non-invasive way without any preparation. This is also valid for fragments or samples.

In this device, the proton beam from an accelerator beam line under vacuum crosses a window of a polymer, aluminum or silicon. The beam spreads as it traverses the atmosphere. The proton

beam is collimated to determine the analyzed area, typically 1–2 mm diameter, but it can range from 0.25–4 mm depending on the purpose of the analysis. If the object is set in front of the beam at a short distance (5–10 mm), the ion beam impinges the object surface with enough energy to induce characteristic X-rays for PIXE analysis. X-ray detectors, typically two, collect the characteristic X-rays emitted by the elements of the material (see Figure 2). Usually, one detector is dedicated to light element detection using a helium jet in the path between the object surface and the detector. This system improves the detection of elements from sodium to iron. Another detector provided with a filter reduces the collection of X-rays of light and major elements in order to detect heavier elements as well as trace elements of the material (Sokaras et al. 2011). The proton beam energy ranges from 2–3 MeV, when the detection limits are the highest for PIXE (some $\mu\text{g/g}$). PIXE measurements take a few minutes per analyzed region.

Other detectors for gamma-rays, scattered protons and light can be set in the external beam device in order to carry out simultaneous PIGE,

Figure 2 External beam setup of the Pelletron Accelerator of Instituto de Fisica, UNAM, during the analysis of a Mayan mask.

RBS, and IBIL. In particular, RBS allows the measurement of light element concentrations, which are significant for matrix corrections, by X-ray absorption, and helps to determine the elemental depth profile. PIXE data prove to be more accurate when light element concentrations are measured.

The analyzed depth depends on the beam energy and on the X-ray absorption for each element in the material. The X-rays of light elements (of lower energy) are more absorbed than the X-rays of heavier elements (of higher energy). Typically, for materials composed of heavier elements (such as metals), the analyzed depth is less than $30\text{ }\mu\text{m}$. For lighter materials (like pottery) the analyzed depth may reach $100\text{ }\mu\text{m}$ for the heavier elements. The analyzed depth is less than the depth reached by the proton beam within the material.

Standard reference materials (SRMs) from NIST or IAEA must be measured under the same experimental conditions. This is necessary to

calibrate the PIXE system and to measure the detection efficiency for X-rays. Some specific SRMs are available for sediments (also useful for pottery), metals (e.g., gold, silver, bronze, and brass), obsidian, glass, and bone, among others.

X-ray intensities are measured from PIXE spectra and calculations are performed considering the beam energy, the geometry of the experimental device, and experimental data from reference materials, in order to measure the elemental composition (wt.%). Several codes, such as GUPIX, have been developed to carry out rapid quantitative analyses.

Since the analyzed depth is determined by the ion beam energy, by modifying the beam energy gradually, it is possible to reach different depths. PIXE spectra will change depending on the layered structure and its composition. Using this method, called differential PIXE, it is possible to measure the elemental depth profile (Calligaro, Gonzalez, and Pichon 2015). This procedure has been developed for technological studies of

metals and pictorial techniques of paintings from the Italian Renaissance. This capability makes PIXE and RBS a unique non-destructive tool to measure the elemental depth profile.

When microanalysis is required, it is possible to produce maps of elemental distribution with a spatial resolution of less than 5 μm under a vacuum, using microprobes with quadrupole optics to focus and scan the beam within 1 mm^2 . Using external microbeams it is also possible to carry out micromapping, but with a lower spatial resolution (30 μm). This analysis is suitable for heterogeneous materials such as minerals and paint layers.

Limitations

Several limitations exist for PIXE. First, objects must be transported to the laboratory. This is not a problem for some samples, but it may be a difficulty for precious objects considering transportation, insurance, storage, handling, and conservation conditions in the laboratory.

To solve this problem, it is possible to perform PIXE using a portable spectrometer with radioactive sources of alpha particles of 5 MeV (Pappalardo et al. 2015). A PIXE spectrum is collected over one hour (depending on the activity of the source); this is an in situ non-invasive method that has been applied to pottery, metallic artifacts, and manuscripts.

Analyzed depth by PIXE also has some limitations due to the X-ray absorption in the materials. This is important for objects composed of layers like paintings and for patinas or plating of metallic artifacts. Analytical information may be limited to the most external layers, depending on their composition and thicknesses, as well as the manufacturing or pictorial techniques.

Ion beam irradiation of some materials can produce dark spots due to defects in the material (e.g., turquoise or glass). Nevertheless, it has been observed that these spots may disappear after some time or under ultraviolet light, recovering its original aspect.

Finally, PIXE is mainly a technique for inorganic material analysis, although it is possible to

study organic materials in some cases, such as amber from its inorganic inclusions.

Applications

Pottery

Ceramics is one of the most abundant materials in the archaeological record. Pottery is made from several clays and temper with slip coatings and pigments at the surface. Elemental analysis of pottery can be used to determine major, minor, and trace elements of the ceramic components. This information is useful for determining the provenance of raw materials, identifying pigments, and studying the manufacture of the pottery.

Ceramic objects and sherds can be analyzed directly with external beams to determine the elemental composition of the ceramic paste, slipware, and pigments. This can be used for homogeneous ceramics, such as Chinese porcelain.

For accurate measurements of heterogeneous paste, the surface of the sherds is eliminated mechanically to take out the painted surfaces, slipware, and surfaces altered by the archaeological context. A small clean fragment is powdered and heated to dry the material and to eliminate organic materials. Homogeneous pellets are prepared with a hydraulic press. Pellets are then irradiated for few minutes to get suitable PIXE spectra. In this way, it is possible to avoid texture and heterogeneity effects of the paste.

After quantitative analyses, elemental concentration data are processed by statistical means such as cluster and factor analysis to determine groups of similar composition. Clusters may be contrasted and interpreted to determine changes in the exploitation of raw materials, to identify local and foreign manufacturing, as well as exchange and trade.

Obsidian and glass

Obsidian is a natural homogeneous volcanic glass. It has been used as a cutting tool and to produce artifacts for offerings. Elemental analysis by PIXE and PIGE has proven to be a powerful method to measure directly the

elemental composition of the artifacts, without any sampling or preparation. Data are useful for sourcing of pieces and to research trade and exchange between different regions. Light elements (e.g., sodium) from PIGE analysis are often important to contrast the material composition. The PIXE-PIGE method has been successfully used for the provenance of obsidians from Mesoamerica and South America, the Mediterranean region, and Oceania.

On the other hand, glass production can be inferred from elemental data, including impurities and trace elements. It is possible to classify glass from the contents of calcium, potassium, and sodium, and to determine exchange and trade. This has been done for glass from ancient Egypt, Roman glass, Byzantine and Islamic tesserae, Renaissance glass from Venice, and medieval stained glass, among other studies (Neri et al. 2016).

Glazed pottery has been extensively studied to determine the composition and technology of the glaze and the pigments. Glazed potsherds and tiles from Spain from the fourteenth to eighteenth centuries were analyzed by PIXE and other methods to understand the evolution of raw materials and manufacturing techniques. From this research, a change in the microstructure was observed from the fifteenth century, while the use of tin in glaze started from the seventeenth century. Other studies of glazed pottery from Italy, Portugal, Egypt and the Islamic world have revealed the composition of green, blue, black, and yellow colors. Surface analyses using PIXE, RBS, and PIGE have contributed to the understanding of the optical properties of glaze to produce a golden luster effect.

Gems and semiprecious stones

Following a similar approach for glass and obsidian, artifacts made with gemstones and precious minerals can be analyzed directly, in particular when the material is homogeneous. This is the case for emeralds, sapphires, and rubies. This approach has been applied to study the exploitation of beds of gems from Asia and Africa, and trade routes to Mediterranean areas and Europe in different historical periods.

Some stones may be heterogeneous; in this case, the use of microbeams for PIXE and IBIL measurements is a suitable analytical strategy to characterize the mineral components of the surface. Jade from Mesoamerica and China, as well as lapis lazuli, has been studied in this way to investigate the provenance of raw materials (Re et al. 2011).

Metallic artifacts

Precious metals are usually well preserved with practically no surface corrosion, but they may have intentional patinas or surface enrichment to change their aspect. Also, metallic artifacts may be melted to produce other artifacts, and the alloys are often mixed. For copper-based alloys, like bronze, the artifacts have patinas or they may be gilded or silvered. Corrosion may be present and may interfere with the examination of the artifacts.

PIXE and RBS are suitable methods to determine the composition of the alloys and soldering procedures (Zucchiatti et al. 2014). Plating, gilding, and patination can be studied using differential PIXE since the metallic surface comprises layers of different compositions. These methods have been applied to artifacts from various historical periods in Europe, Iran, India, Mesoamerica, and Colombia. Also, the surface enrichment of coins has been studied to understand the economic development of various societies.

Despite the problem of remelting, sourcing of precious metals has been successfully determined by PIXE and other methods to establish the circulation and production of coins and other artifacts.

Microbeams have been used to characterize surface treatments and plating of metallic threads in historical textiles. These analyses have been carried out on samples under vacuum as well as directly on objects using external beams.

Manuscripts

Documents and ancient books have been studied by the analysis of inks, paper, and decorations. In particular, manuscripts from Europe and Asia have been effectively examined by PIXE with external beams to determine the materials used

to write and decorate the manuscripts, modifications and writing chronologies, and the printing procedures for books.

Paintings

The main difficulties for painting studies are the handling of the artworks, experimental conditions to avoid damage, and the analyzed depth limits (Calligaro et al. 2015). For small paintings, external beams and microbeams are suitable to characterize pigments at the surface. If the paint layers are not too thick (less than 30 μm), differential PIXE can provide insights into the sequence of layers and their composition.

Several studies on painting fragments and samples have been carried out for mural paintings and pigments. Examinations provide proper identification of inorganic pigments, but also pigment sources can be discriminated using PIXE.

Other materials

Bone remains are important materials for archaeological purposes, and can be used, for example, in palaeodiet studies by using iron, zinc, strontium, and barium contents in long bones. Teeth and hair may provide information about health and exposure to lead and other contaminants. PIXE is also suitable for discriminating between bone, ivory, and antler, by using the contents of calcium, magnesium, fluorine, and strontium.

Diagenesis can also be characterized by PIXE. This information is important for selecting samples for dating and conservation.

Pyrotechnology of Cements

RAFAEL FORT GONZÁLEZ and
DUYGU ERGENÇ

Instituto de Geociencias (CSIC-UCM), Spain

Beginning with the ancients, humans have been using different types of cements to improve construction techniques and building habitability. The initially used natural binders of rammed earth, clay, and tar later gave way to the application of pyrotechnology to limestone and gypsum which are heated to below melting point temperatures to improve their quality and durability. The resulting cements, which revolutionized construction in ancient societies, are still in use today.

Mortar and plaster are pyrotechnological outputs whose raw materials are quarried from carbonate rock and gypsum outcrops and must be heated to obtain the end product. When gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is heated between 100 and 150 °C it loses part of its molecular water and forms the hemihydrate ($\text{CaSO}_4 \cdot 1/2\text{H}_2\text{O}$), and if the temperature reaches 250 °C, it totally loses the molecular water and anhydrite (CaSO_4) formation occurs. When water is added to these finely milled products they are rehydrated, and moldable paste with high workability forms. These gypsum mortars (known as Plaster of Paris) were the first in history to be used in wall coatings due to their low firing temperature (Carran et al. 2012).

Since ancient times, one of the most widely used pyrotechnological cements has been lime. Lime mortars have four constituent raw materials: binder, aggregates, additives, and water. The binder is obtained from carbonate rock (CaCO_3 , limestone and dolomite), crushed and heated to temperatures of 600–900 °C to remove the CO_2 from the calcium or dolomitic carbonate. Known as calcination, the process yields calcium oxide (CaO), that is, quick or burnt lime:

Quick lime is then hydrated or slaked with water, an exothermal reaction ($>90^\circ\text{C}$) that forms calcium hydroxide (portlandite), a hydrated lime powder or slaked lime paste:

Over time, as this calcium hydroxide reacts with atmospheric CO_2 , it converts to calcium carbonate (CaCO_3) (equation (3)). Depending on environmental conditions, the CaCO_3 can precipitate as several polymorphs, evolving from the least to the most stable (vaterite, aragonite, and calcite, respectively). Calcite, the end product of what is known as carbonation and the form extant in lime mortar, has the same chemical composition as the original rock.

In other words, lime mortar pyrotechnology can be divided into three stages—calcination, hydration, and carbonation—which over time yield a compact, highly deterioration-resistant material.

Aerial lime carbonates in the absence of moisture. Such hydraulicity was attained by adding pozzolans, silica- and alumina-high compounds that react with lime in the presence of water or high humidity to form calcium silicate (CSH), calcium aluminate (CAH), and calcium aluminosilicate (CASH) hydrates. The result is a stable, mechanically strong binder that adheres firmly to the aggregate. Hydraulic lime, which already contains those hydrates itself, sets in the presence of water. Its discovery by John Smeaton in 1756 revolutionized ancient construction technology, for it could be used in moist environments or even underwater, to the benefit of civil works such as aqueducts, bridges, vats, ports, and roads across marshes (Elsen, Van Balen, and Mertens

2012). Hydraulic limes were classified by Luis Vicat as “feebly,” “moderately,” and “eminently” hydraulic, depending on the clay impurity content. For coatings and grouts, sometimes a lime–gypsum mixture is used to improve their setting.

Different ancient societies produced lime using local natural resources and by applying autochthonous technology, subsequently relayed across trade routes and via conquest and colonization. Pyrotechnology continued to evolve in historic times, driving the development of new materials, such as Portland cement in the nineteenth century. The archaeological study of these materials is of great interest, for it sheds light on the technological and trade-related evolution of many societies.

The earliest findings on pyrotechnology products came from Anatolia in Göbeklitepe (tenth to ninth millennium BCE) as lime and as gypsum and marl coatings on rammed earth walls in Çatalhöyük (6000–7500 BCE) (Schmidt, Hurd, and Thompson 2011; Mellaart 1967). The technology appeared later with lime use with organic additives in ancient China beginning at about 1000 BCE. In Europe, lime mortar was not extensively used until it was adopted by the Greeks and later by the Romans around the first millennium BCE. It was developed more after around 500 BCE when the Greeks improved aerial lime by adding pozzolans from the Santorini volcanic area (Ritzouli, Stefanidou, and Konopisi 2016). It was widely used as a mortar and concrete by the Imperial Romans, who prepared it initially with volcanic ash from the Pozzuoli region near Mount Vesuvius (Carran et al. 2012). With the fall of the Roman Empire, the use of mortar in western medieval Europe declined. A less-meticulous selection of materials yielded products of lower quality than Roman concrete. Roman tradition was kept alive in eastern Europe, however, by the Byzantines and later the Ottomans.

Roman cement, contrary to its ambiguous name, or so-called natural cement was discovered by James Parker and started to be used in 1796 in England. Natural cement whose advantage was its fast setting (less than 12 h) was manufactured from marly limestone (25–40% clay). Calcination lasted between 8 and 20 h at a temperature of 800–1200 °C (Varas, Alvarez de Buergo, and Fort 2005).

These cements were quickly replaced by Portland cement, whose industrial production began in 1845 in England with Isaac Johnson, after Joseph Aspdin’s patent in 1824. Its raw material was pure limestone (80–75%) and clay (20–25%), calcined at temperatures above 1300 °C, which allowed a shorter setting time, at least 8 h.

Both types of cement are differentiated by their mineralogy, since in natural cement, belite (dicalcium silicate, C_2S) is the main phase which gives late strength, while in Portland cement, the main phase is alite (tricalcium silicate, C_3S) which gives early strength. The calcination process of natural cement is carried out in vertical kilns, as so the lime mortars, but an innovation with Portland cement is the use of subhorizontal rotary kilns in which the temperature increases from the entrance to the exit, reaching between 1350 and 1450 °C, where the components melt. When cooled, clinker is obtained. This product consists of 60 percent tricalcium silicate ($3CaO \cdot SiO_2$, C_3S), 20–30 percent dicalcium silicate ($2CaO \cdot SiO_2$, C_2S), 7–14 percent tricalcium aluminate ($3CaO \cdot Al_2O_3$, C_3A), and 2–12 percent tetracalcium ferroaluminate ($4CaO \cdot Al_2O_3 \cdot Fe_2O_3$, C_4AF). Finally, to improve its qualities, a small percentage of gypsum and additives (ash, slag, etc.) are added. The obtained binder is mixed with aggregates of different size and composition and water to form an applicable paste. With the reaction with water, calcium silicates (C_2S , C_3S) hydrate and cause the formation of tobermorite ($Ca_5Si_6O_{16}(OH)_2 \cdot 5H_2O$, CSH); likewise, in the presence of gypsum, calcium hydroxide and tricalcium aluminates (C_3A) favor the formation of ettringite ($Ca_6Al_2(SO_4)_3(OH)_{12} \cdot 26H_2O$).

Deploying analytical techniques to determine the type of limes used in the built heritage, archaeologists can establish construction periods and relative dating of the various parts of a building. Macroscopic characterization provides organoleptic information; however, it does not suffice to type mortars. Physical–chemical analyses must be conducted to confirm the type of mortars.

Polarized light microscope-based petrographic studies of thin mortar sections reveal the composition and form of the aggregates and their particle size distribution. This method can be

used to examine the interface between the mortar and adjacent materials, identify binder type, aggregates, clinker nodules, and lime lumps, and determine the percentage of pores and the presence of new mineral phases generated during carbonation. It also delivers an estimate of the binder:aggregate ratio.

X-ray diffraction (XRD) is a technique particularly apt for determining the nature of binder and aggregate composition after the two components are separated. It is limited inasmuch as it cannot identify amorphous or noncrystalline mineral phases or any with a content of less than 5 percent, or differentiate between carbonated binder and limestone aggregate.

In contrast, based on crystal habit, scanning electron microscopy (SEM), together with energy dispersive X-ray analysis (EDX), can distinguish the carbonate mineral phase formed from any remaining noncarbonated portlandite crystals. It also determines elemental chemical composition, which is important to establish the size and shape of the crystals of hydraulic phases which have direct impact on the mortar's quality. Since carbonation takes place gradually from the surface inward, SEM can also be used to establish the depth of the carbonation. Phenolphthalein ($C_{20}H_{14}O_4$), another reliable indicator of carbonation, detects the presence of portlandite by dyeing the respective area pink, whereas no color change in the mortar denotes full carbonation.

Thermogravimetry differential thermal analysis (TG-DTA) is yet another indispensable technique for determining mortar hydraulicity. It measures sample weight loss with rising temperature due to the loss of water and CO_2 attendant upon the decomposition of $CaCO_3$ in the mortar.

Weight loss at temperatures of under $120^\circ C$ is attributed to hygroscopic water in the mortar and loss at $200\text{--}600^\circ C$ primarily to bound water in hydraulic compounds (CSH, CASH, and similar). Weight loss at over $600^\circ C$ is the outcome of $CaCO_3$ decomposition (Moropolou, Bakolas, and Bisbikou 2000). The $CO_2:H_2O$ ratio provides a measure of mortar hydraulicity. The higher the ratio, the lower the hydraulicity.

XRF and inductively coupled plasma mass spectroscopy (ICP-MS) can be used to determine the percentage of each mortar constituent, as

well as the cementation index (CI) described by L. Vicat and the hydraulicity index (HI) later proposed by E. C. Eckel:

$$CI = \frac{2.8SiO_2 + 1.1Al_2O_3 + 0.7Fe_2O_3}{CaO + 1.4MgO} \quad (4)$$

$$HI = \frac{SiO_2 + Al_2O}{CaO} \quad (5)$$

Lime mortar/cement can be characterized mineralogically and chemically by the techniques mentioned above to determine the degree of carbonation and type of lime used. Other tests can characterize the petrophysical properties of mortars by determining compactness, effective porosity, pore size distribution, and air permeability. These, together with ultrasound wave velocity and surface hardness tests, are instrumental in defining the degree of deterioration of the mortars studied. Besides, being nondestructive, some can be conducted at the archaeological site itself, with no need to take samples.

Portland cement was often used in archaeological and architectural heritage restoration, because it was cost efficient as it took less time to set, and it dominated the market; however, it has been revealed that it can cause damage due to its higher rigidity and impermeability, and it can generate very harmful salt phases. Moreover, alkali minerals in these cements decrease the durability and may lead to expansive compounds which favor the corrosion of metallic elements in humid environments. Under these circumstances, identification/differentiation of the cement and mortar is necessary to rescue the damaged heritage.

Raman Spectroscopy and Material Analysis

EDGAR CASANOVA-GONZÁLEZ

Universidad Nacional Autónoma de México, Mexico

Nondestructive analysis on heritage materials

Not only is the detailed characterization of the constituents of heritage objects important for understanding the material and technological knowledge behind its manufacturing, but also the materials used can act as both a chronological or geographical marker—and help establish the adequate policies and procedures for its restoration and conservation. To fulfill such a goal, many analytical techniques have been applied, with the combination of several techniques being the most useful approach. The methodologies have evolved from classical analytical chemistry methods, such as high-performance liquid chromatography (HPLC) and gas chromatography mass spectroscopy (GC-MS), to the preference for nondestructive techniques, which can be complemented with destructive analysis on selected samples. Technological advances have led to the miniaturization and portability of spectrometers, allowing in-situ analysis to be carried out in many cases.

A combination of imaging and spectroscopic analysis is usually preferred in order to retrieve as much information as possible from the studied object. A general inspection through imaging techniques may include visible, infrared, and ultraviolet light imaging, false-color infrared imaging, and multispectral imaging. The most common combination of spectroscopic techniques comprises elemental analysis with X-ray fluorescence (XRF), scanning electron microscopy energy dispersive X-ray spectroscopy (SEM-EDX), and particle induced X-ray and gamma-ray emission (PIXE and PIGE); structural techniques, mainly X-ray diffraction (XRD); and both organic and inorganic compound

analysis using fiber optic reflectance spectroscopy (FORS), visible light fluorescence spectroscopy, Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy.

The Raman effect

The Raman effect was first reported by C. V. Raman and K. S. Krishnan in 1928 (Raman and Krishnan 1928) and, later that year, by G. Landsberg and L. Mandelstam (Landsberg and Mandelstam 1928). Raman was awarded with the Nobel Prize in Physics in 1930 “for his work on the scattering of light and for the discovery of the Raman effect.” The effect consists of the inelastic dispersion of a photon by an electron in a molecular bond. When light is dispersed by an atom or molecule, most of the photons undergo an elastic dispersion—that is, the dispersed photon has the same frequency and energy as the incident photon—known as Rayleigh dispersion. Around one in ten million incident photons suffer inelastic dispersion, providing it with a different energy than the incident photon. The dispersed radiation gives information about the composition of the studied object, since its shift in frequency—known as Raman shift—is related to the type of bonds and the electronic environment where the interacting electron is located. Thus, the resulting spectrum can be considered a vibrational signature of the molecule (Vandenabeele 2013).

There are two possibilities when the Raman effect occurs, as the photon can be dispersed with a lower or higher energy than the incident one (Figure 1). Such phenomena are known as Stokes and anti-Stokes dispersion, respectively. In Stokes dispersion, the incident photon interacts with an electron located on the ground vibrational level, which absorbs all of the energy from the photon and reaches a higher, excited energy level. For the electron to return to a more stable state at a lower energy, the molecule releases a photon with an energy equal to the difference between the excited level and the first vibrational level, where the electron is finally at

Figure 1 Vibrational transitions associated with the Raman effect.

rest. On the contrary, for anti-Stokes dispersion to take place the incident photon must interact with an electron located on the first vibrational state. The electron reaches an excited state and the molecule returns to a stable configuration by releasing a photon with an energy equal to the difference between the excited and ground states, which is higher than the energy of the incident photon. At room temperature, only 1 percent of the electrons are on the first vibrational state, so the Stokes dispersion is 100 times more probable—and intense—than the anti-Stokes and is most commonly employed for Raman spectroscopy.

Instrumentation

The basic components of a Raman spectrometer are a laser source, a system for illuminating the sample, and a suitable detector (a spectrometer or spectral analyzer). Such instruments must eliminate the very strong signal from the Rayleigh dispersion and detect the bands that correspond to the Stokes—or anti-Stokes—dispersion. The most common laser wavelengths used are 532 and 785 nm, but 485, 514, 633, and 1,064 nm are also utilized. The analysis area ranges from 1 to 5 mm, without the use of a microscope, to a few micrometers for microscope-coupled benchtop spectrometers.

Raman spectrometers' size ranges from small handheld instruments to benchtop equipment. Handheld analyzers are often very light, easy to use, and designed for specific applications, usually for the identification of raw materials in industry and for the detection of drugs and explosives. More complex analysis, involving unknown materials—or materials that are not included in the equipment's database—can be difficult to perform.

A second category of portable spectrometers comprises instruments weighting around 2–5 kg. They can be used both in the laboratory and in situ; a microscope can be mounted on these instruments or come already equipped with a built-in microscope, and they are usually suitable for analyzing liquid and solid samples. Although their performance cannot be compared with benchtop instruments, portable spectrometers successfully answer a wide range of investigative questions.

Benchtop spectrometers constitute the third category. Among their capabilities are the high sensitivity and spectral resolution, the inclusion of powerful microscopes, and multiple laser wavelengths. Many of them can be coupled to external fiber optic probes for the analysis of large objects. In most cases, the studies must be performed on small samples, but this disadvantage is compensated by the quality of the information that can be gathered.

Limitations and alternatives

Raman spectroscopy faces two important limitations. As the Raman effect has a low probability to occur, Raman signals are often weak and difficult to observe. This can be overcome by increasing the laser power, the acquisition time, or both, but both solutions also increase the chance of damaging the analyzed object due to the amount of energy deposited in the analyzed area by the laser. A second drawback is the interference of fluorescence caused by the laser on a wide variety of substances, mainly organic compounds. The intensity of this fluorescence background can even prevent the observation of the Raman bands from the object (Moskovits 2005).

Such problems have been addressed in different manners. The selection of the laser wavelength can be crucial in increasing the intensity of the signal by provoking a resonant Raman effect—when the incident energy is close to an electronic transition of the studied molecule—or in diminishing the fluorescence, as laser frequencies in the infrared region are less likely to cause such phenomena. Laser-induced damages can be avoided by carefully controlling the laser power and acquisition time or, in some cases, by coupling a helium beam to the spectrometer. Spectrum processing using mathematical reconstruction algorithms is also useful for eliminating the fluorescence and revealing the hidden Raman bands. Another option, which is being increasingly explored, is the acquisition of the Raman spectrum in the anti-Stokes region, but this has not yet been extensively applied.

Perhaps the most common alternative is the use of surface-enhanced Raman spectroscopy (SERS), which takes advantage of the huge amplification of the Raman signal that occurs when the analyte is in close contact with silver or gold nanoparticles of a particular size and shape (Fleishmann, Hendra, and McQuillan 1974; Aroca 2006). A second benefit of SERS is a drastic decrease of the fluorescence, leading to the acquisition of high-quality spectra. The preparation of SERS substrates is a vast field of research. Nevertheless, the need for direct contact between the nanoparticles and the studied object makes the application of SERS challenging in the field of cultural heritage. Some alternatives are

the inclusion of the nanoparticles on detachable gels, or the preparation of nanoparticle-coated optical fibers in order to produce tip-enhanced Raman scattering (TERS).

Applications

Since the late 1990s, Raman spectroscopy has emerged as one of the most important and effective techniques for the identification of pigments and dyes in heritage objects, due to its high specificity, small amount of sample—when needed—and its feasibility for nondestructive in-situ analysis. Significant efforts have been devoted to the conformation of spectral databases that include minerals, pigments, and natural and synthetic dyes. Most of these databases are available online and are of vital assistance in the identification of materials via Raman spectroscopy.

The technique has been successfully employed in a wide range of studies, including medieval pigments, panel and easel paintings (ancient and modern), dyed textiles, Egyptian papyri, Punic decoration materials, Iraqi stuccoes, and mural paintings from Pompeii. In the Mesoamerican area, Raman has been especially useful in the material characterization of dyes and pigments, including pre-Hispanic mural paintings and codices, and in mineral characterization, mainly of green stone artifacts.

In the field of archaeology, Raman spectroscopy is particularly suitable for the identification of minerals present on walls and stuccoes, for the characterization of lapidary objects, the identification of pigments, dyes, and other constituents of mural paintings, manuscripts, textiles, ceramics, and the determination of corrosion phases in metallic objects (Edwards and Chalmers 2005). Another application is the mapping of small areas. The laser—or object—can be scanned over the object surface, and the intensity of a Raman band of a given molecule can be translated into a color scale and plotted in a 2D graphic, generating an image that contains information on the distribution of such molecules in the analyzed area. Depending on the size of the studied area and the spatial resolution of the analysis, Raman mapping can be time-consuming.

MICHAEL MELCHER

Institute of Science and Technology in Art, Austria;
Institute of Applied Statistics and Computing, Austria

Electron microscopy (see ELECTRON MICROSCOPY IN CONSERVATION) in different instrumental configurations has become one of the most versatile characterization tools in the investigation of archaeological materials. Within this frame, scanning electron microscopy (SEM) is universally employed to identify the nature of materials and provide chemical compositions. Indeed, in SEM instruments the coupling of imaging, thanks to the detection of backscattered or secondary electrons, and chemical analysis, thanks to the detection of excited secondary X-rays, represent a powerful tool for the investigation of virtually any kind of material. This entry presents case studies related to ancient glass (see GLASS AND FAIENCE) samples.

Authenticity of archaeological glass

Applying SEM with with energy dispersive X-ray spectroscopy (SEM-EDX) to the study of archaeological glass, we have to keep in mind that it has a history of more than 3,500 years. Nevertheless, the technology of glass production has not changed so much: By heating a mixture of sand (SiO_2), natron (Na_2CO_3), and lime (CaCO_3), a stiff liquid was obtained, which was wound around a core of clay and dung and then reheated in order to smooth the surface. Core-forming remained the dominant technique for producing glasses until the second or first century BCE, when it was found out that a molten blob of glass can

easily be formed in various shapes by blowing short puffs of air into it—thus glassblowing was discovered. From then on, glass became more widely used, as it could be offered for a reasonable price (Frank 1982; Davison and Newton 1989).

According to Zachariasen (1932), pure silica glass has an amorphous (noncrystalline) structure and can be described as a three-dimensional network of $[\text{SiO}_4]$ -tetrahedra. Besides the network former silica (SiO_2), so-called network modifiers (alkali and alkaline earth elements such as Na, K, Ca, and Mg) are added—mostly in the form of their oxides or carbonates—to the batch of raw materials in order to reduce its melting temperature. These compounds break up the silicate network and form terminal $-\text{Si}-\text{O}-\text{M}$ ($\text{M} = \text{Na}^+, \text{K}^+$) or bridging $-\text{Si}-\text{O}-\text{M}-\text{O}-\text{Si}$ groups ($\text{M} = \text{Ca}^{2+}, \text{Mg}^{2+}$). The formation of these so-called nonbridging oxygen sites widens the silica network. The nature and concentration of these network modifiers play a decisive role in the stability and durability of the glasses. Further ingredients, such as colorants, decolorants, and fining agents are present only in minor amounts in the glass (see GLASS COLOR).

SEM-EDX studies could be performed on fragments of ancient glass excavated since the 1950s at Hanghaus I, a Roman insula in Ephesus, Turkey, which was originally built in late Hellenistic times as a luxurious peristyle house, and served, following some earthquakes, from the third century CE as a more simple accommodation unit. Among numerous other findings, more than 1,000 glass objects and glass fragments (Figure 1) were excavated dating from the late Hellenistic to the late Ancient period (i.e., between the middle of the second century BCE and the seventh century CE). A representative cross-section of 106 samples taken from these objects was subjected to chemical analysis. The main objective was the chemical characterization of these glasses, which were archaeologically preclassified into 19 groups (“form-groups” (FG)) based on their typological characteristics such as design, usage, and decoration (Czurda 2007).

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0528

As all fragments showed more or less thick weathering crusts on their surfaces due to burial for many centuries (Figure 1), small splinters were cut off using a low-speed diamond saw, embedded in resin, and polished with SiC paper perpendicular to their surfaces, enabling the investigation of the unaffected bulk material. The results described in detail in the literature showed 12 major and minor constituents (oxides of Na, Mg, Al, P, S, Si, K, Ca, Ti, Mn, Fe, and Cl) and eight trace elements (oxides of Cr, Co, Ni, Cu, Zn, As, Pb, and Sr). All glasses are of the soda-lime-silica type with SiO₂ concentrations between 64.6 and 77.8 wt%, Na₂O from 10.5 to 18.7 percent, and CaO ranging from 4.6 to 11.3 percent. The contents of K₂O and MgO are below 1 percent for nearly all samples, those of P₂O₅ and SO₃ in most cases below the detection limit, with maximum values also around 1 percent. These low levels of MgO and K₂O argue for the use of soda (a mixture of NaHCO₃, Na₂CO₃, and some other Na-salts) as a flux, typical for glass produced in the Hellenistic and Roman periods.

For reasons of data reduction and to eventually observe cluster patterns in the sample population, factor analysis (FA) for a better interpretation of the results was applied to the original compositional data of Na₂O, MgO, Al₂O₃, Cl, K₂O, and CaO. Scatter plots of the first two factors (representing more than 60% of the original variation in the dataset) help to decide whether the archaeologically defined form groups eventually coincide with the compositional clusters. The loading plot (Figure 2, right) indicates that factor no. 1 mainly contains contributions of Al₂O₃, K₂O, and CaO (positive correlation) and Cl (negative correlation), whereas factor no. 2 “consists” primarily of Na₂O and MgO, both showing a positive correlation. Indeed, the FA score plot (Figure 2, left) exhibits strong clustering: for some form groups (e.g., nos 1, 7, 15, and 19) a single “chemical cluster” (i.e., based on the factor scores of the corresponding samples and hence on the chemical composition) is obtained, whereas some other FGs (e.g., nos 8, 14, 16, and 17) seem to consist of a number of subgroups. The combined archaeological, typological, and statistical results allow for classification of the objects into so-called glass groups (GG), now also exhibiting similar chemical compositions.

Degradation of historic glass

As relicts of the past, archaeological objects are rarely found in their original state—their condition has been altered depending on the nature of the material used and the environment. The exposure of glass to moist air or soil leads to the formation of a so-called leached layer on the surface, resulting in an iridescent appearance, as can be seen in Figure 1, left image. The main reason is an ion exchange mechanism occurring in neutral and acidic media involving the mono- and bivalent network modifier ions (e.g., Na⁺, K⁺, Ca²⁺, or Mg²⁺) in the glass and certain hydrogen-bearing species such as H⁺ or H₃O⁺ or even molecular water of the attacking medium (Equations 1a and 1b). Consequently, the glass surface is depleted in alkali and alkaline earth, while the silicate network remains essentially unaltered. The thickness of this hydrogen-rich layer depends on the conditions: the nature and concentration of the attacking soil, the glass composition and its initial surface structure and morphology, and various other conditions such as the temperature or exposure time.

Similar effects can be observed on medieval stained-glass windows exposed to the ambient atmosphere, as a thin water layer resulting from air moisture, fog, or even rain may be adsorbed on the glass surface, allowing the ion exchange mechanism described above (Figure 3). During

Figure 1 Glass fragments excavated at Hanghaus I in Ephesus, Turkey. Left: Shell with hanging lip and inlaid decor; right: cup foot with button.

the Romanesque and Gothic periods wood ashes (mainly consisting of K_2CO_3) were added to the sand in contrast to the glasses manufactured in the ancient Mediterranean region, where soda present e.g. in the ash of sea-plants or taken from the Wadi el Natron (Egypt) was used as a flux. Its unfortunate consequence is the poor durability of the potash-lime-silica glass, which causes many of these medieval stained glass objects to perish.

Additionally, atmospheric pollutants such as the acidifying gases CO_2 , SO_2 , NO_2 , and O_3 or airborne particulate matter may dissolve in the thin water film, causing an increase in the H^+ concentration and hence accelerating the ion diffusion. As soon as the temperature increases, the water film may evaporate, leading to the precipitation of crystalline weathering products on the glass surface. The chemical composition of

these weathering products is mainly determined by the glass composition and the atmospheric gases. On the surfaces of potash-lime-silica glass with medieval composition, mainly syngenite ($K_2SO_4 \cdot CaSO_4 \cdot H_2O$), gypsum ($CaSO_4 \cdot 2H_2O$), and arcanite (K_2SO_4) can be identified by X-ray diffraction as well as SEM-EDX as dominant weathering products, as depicted in Figure 4. The morphology of the formed weathering products varies from plate-like shape to needles and lanceolate crystals. Furthermore, chlorides of Na and K, Si-containing compounds, weathering products containing K, Ca, and C (possibly carbonates, oxalates, or other organic compounds), and various depositions, often rich in Al and Fe, can be identified. As mainly K-containing weathering products can be detected, a preferential leaching of this element compared to the other

Figure 2 Score (left) and loading (right) plots of the factor analysis results: Factor 1 is determined by concentrations of Al_2O_3 , K_2O , CaO , and Cl , whereas factor 2 contains mainly contributions of Na_2O and MgO .

Figure 3 SEM micrograph of the cross-section of a naturally weathered medieval glass (a) with corresponding elemental mappings of K (b), Ca (c), and Si (d).

network modifier ions in the glass (Ca, Na, and Mg) may be assumed.

Analytical investigations have become an important part in the interdisciplinary cooperation of our heritage, if the specific technique can be applied in a nondestructive or even noninvasive way to an archaeological object. Among the large variety of methods available in materials science, as demonstrated in the previous examples, SEM-EDX can be useful for the purposes of assigning, for example, archaeological glass to a specific place or studying the degradation process of archaeological glass buried for even two millennia, as well as of medieval stained glass exposed to the ambient atmosphere for centuries. In this context, modern (multivariate) statistical methods often prove to be useful to achieve additional insights into the data obtained and can support an archaeologist dealing, for example with dating of objects.

Additionally, the results obtained from such studies are indispensable for the development

of conservation and preservation strategies. At the moment, there are several conservation treatments proposed and in practice for preserving our heritage in the field of glass, especially for outdoor objects exposed to the ambient atmosphere: protective coatings with polymers, especially silicon-organic compounds, coating with inorganic materials by applying the sol-gel glassy process or sputtering an inorganic layer on the glass surfaces, and protective outdoor glazing. Additionally, such treatments should provide increased chemical resistance of the glass substrate and sufficient stability against light while preserving the transparency of the object at the same time.

For museums' objects, monitoring of several environmental parameters—such as the relative humidity in the ambient atmosphere, the concentrations of acidifying gases SO_2 , NO_2 , and O_3 , and particulate matter—is of high importance. Glass sensors were developed as dew point sensors with the aim of better understanding the environmental influence on glass surfaces. Such

Figure 4 SE image of a weathered surface of potash-lime-silica glass (top) and corresponding X-ray mappings of the elements K (row 2 left), Ca (row 2 right), S (row 3 left), and Al (row 3 right), indicating formation of syngenite ($\text{K}_2\text{SO}_4 \cdot \text{CaSO}_4 \cdot \text{H}_2\text{O}$) and deposition of an Al-rich atmospheric particle.

sensors allow for the detection of condensation on the glass surface, which might accelerate the glass weathering process. Using such sensors, it could also be shown that protective glazing systems for stained glass reduce the danger of condensation on the internal sides of the windows and the total time of the presence of high values of relative humidity in air in contact with the protected window.

Soil Chemistry in Archaeology

RICHARD E. TERRY and
BRYCE M. BROWN
Brigham Young University, USA

Archaeologists look for and examine artifacts to interpret the activities of ancient peoples. However, most material goods and implements used anciently were made of perishable organic substances that did not survive into the artifact record. Perishable organic implements and food may have initially accounted for as much as 90% of an ancient household's artifact inventory (Dahlin et al. 2007). Organic substances eventually decompose to gaseous and soluble substances and are lost to the atmosphere or are leached out of the soil by percolating water, but phosphorus (P) and many trace nutrients—including iron (Fe), copper (Cu), manganese (Mn), and zinc (Zn)—are adsorbed onto soil particles or are precipitated as insoluble compounds and remain for centuries at the location of ancient use. These and other chemical residues of human activities serve as invisible indicators. Many human activities leave behind chemical residues of those activities. By understanding the chemical markers of specific human activities, we can better understand ancient societies through the study of soil organic matter, trace elements, and other nutrients and metals. The architectural, artifactual, and soil chemical data obtained from ancient activity areas provide a robust record of ancient lives.

There are both differences and similarities between the natural soils and the anthropogenic floor surfaces found at areas of ancient human activities. In many parts of western North America, Mexico, and Central America, the major soil parent materials are calcareous sediments and weathered limestone. Stucco and plaster floor

surfaces were often derived from burnt limestone (Barba 2007). During centuries of abandonment the processes of weathering of lime stuccos and plasters yield calcareous soils. Both the soils and the weathered floor surfaces tend to be highly calcareous, with neutral to alkaline pH. The high pH and prevalent calcium and magnesium ions of the soils and floors render anthropogenic P and metal ions insoluble. Stucco and plaster floors were made of burnt lime and limestone gravels that are normally much lower in P, Fe, Cu and other metals of interest than are natural soils (King 2008). The clays and organic matter of soils contain a reservoir of fixed and adsorbed nutrients, therefore natural soils are poor control samples for the estimation of background concentrations of anthropogenic elements. A better estimation of background levels of elements in floors is provided by the levels in samples lowest in concentrations of respective elements (King 2008; Dahlin et al. 2007; Fernandez et al. 2002; Terry et al. 2004).

Soil sediments and anthropogenic floors can bury and provide protection for pollen, phytoliths, bones, architectural components, and nonperishable artifacts over sequential occupations, but the complex chemical and physical processes of soils allow for the accumulation and storage of the chemical residues of those occupations. There are a variety of soil characteristics and chemical analyses that can be used to examine the chemical signature of those activity areas. The roles of specific soil processes in preserving chemical residues of ancient activities are discussed below.

Inorganic soil components

Soils consist of varying proportions of sand, silt, and clay, as well as soil organic matter or humus. The greater portion of fine silts and clays determines the relative surface area of the soil particles. Surface area is important for water retention

and adsorption of organic and inorganic chemical residues.

Ion exchange is the interchange between an ion in solution and on a charged surface. Cations are exchanged on the surfaces of clay minerals and organic matter. The large specific surface area, broken edges, and imperfections in crystal formation within the highly variable soil environment can impart negative charge to the clays. The positively charged cations of the soil solution are attracted to the negative charges on clays and humus. The maximum adsorption of readily exchangeable cations on soil surfaces is termed the cation exchange capacity (CEC). The sum of the cation exchange sites on surfaces is expressed as centimols (cmol) of positive charge per kg. When an ion is replaced on the soil surface, it must be replaced by an equivalent amount of charge to meet the electroneutrality requirement. Whenever an ion is displaced from an exchange site, there is a charge imbalance on the surface of the exchanger, and another ion from the soil solution will immediately exchange place. For example, if a calcium (Ca^{2+}) ion is displaced, it must either be replaced by an ion with a 2+ charge such as magnesium (Mg^{2+}), or two ions with a 1+ charge such as ammonium (NH_4^+).

Soil organic matter

Soil organic matter (SOM) has large adsorptive surface area and high cation exchange, and plays an important role in soil chemistry. SOM consists of many diverse types of organic molecules that react with each other and with the mineral fraction of the soil, making it a complex substance to study. Soil organic matter includes well decomposed humus as well as partially decayed organic tissues from plant and animal detritus.

SOM has several archaeologically important effects on soil chemistry, including chelation, cation exchange, and interactions with organic chemicals. Because of the high specific surface area and local surface charges, SOM has an extremely high CEC. SOM also interacts with organic chemicals and affects their bioactivity, persistence, and biodegradability.

Sorption

Sorption consists of both absorption, the process by which a substance is taken up by and incorporated into a bulk volume, and adsorption, the process by which a substance accumulates at the interface of a solid surface. Adsorption is one of the most important phenomena that occur in soil as it affects the quantity and availability of plant nutrients, metals, and other organic chemicals in the soil. Chemical and physical forces both play important roles in the adsorption of solutes to a mineral surface.

Anthropogenic substances that are retained in the soil

Phosphorus

Soils and floors of ancient human habitations are often elevated in phosphorus concentrations. As hunters, gatherers, and farmers harvested foodstuffs from outside the habitation zone and brought them in to support the nutritional needs of humans, carbon, nitrogen, phosphorus, sulfur, cations and other essential elements were brought into food preparation, consumption, and waste disposal areas. In climates that are cold or relatively dry, many of these nutrients remain in the soil and can be examined as signatures of ancient human activities. In warm and humid climates, most of the carbon, nitrogen, and sulfur have been subjected to microbial decay and have either volatilized to the atmosphere or have been leached out of the soil along with some of the soluble cations by percolating water. Phosphorus and several of the trace elements have low solubility and tend to remain in the soil at the locus of use for centuries. Zones with elevated P concentrations were most likely associated with food preparation consumption and waste disposal activities. Linear patterns of high P in open plaza soils and floors have also been interpreted as zones of vegetable and fruit marketing (Dahlin et al. 2007), feasting activities (Wells 2004), and food storage. Areas of low P concentration have been interpreted as pathways and sleeping areas (Fernández et al. 2002; Terry et al. 2004).

Trace elements

Some of the trace elements in soils at low concentrations are micronutrients that are necessary for plants and animals to live. In high concentrations, however, they are often toxic to living creatures. The micronutrients include Fe, Cu, Mn, and Zn. Heavy metals are those heavier than Fe and include cadmium (Cd), chromium (Cr), cobalt (Co), mercury (Hg), nickel (Ni), and lead (Pb). Ancient people often sought out rocks and minerals for the manufacture of lithic tools, paints and pigments. Some of the micronutrients were used for red pigments, including the iron oxide ochers, mercuric sulfide of cinnabar and vermillion. Manganese oxides form black pigments. Elevated concentrations of these elements in activity areas can give us a further insight into what different areas may have been used for.

Total or extractable element analysis?

Total elemental analysis of P and trace elements can be obtained by X-ray fluorescence (XRF), or by digestion of the sample in strong acids with element analysis by inductively coupled plasma atomic emission spectrometry (ICP-AES). Use of the hand-held, portable “pXRF” works well for many of the heavy elements that emit strong X-rays, but high error rates and interferences have been reported with the measurement of lighter elements (Coronel et al. 2014). Total digestion of samples with strong acids for ICP-AES analysis is both costly and hazardous. Not only do the elements of anthropogenic origin appear in total analysis, but the elements contained in the soil parent materials and ancient humus are also measured. In many cases the small anthropogenic deposition is masked by much larger levels of some elements that were native to the soil or floor materials.

Element extraction procedures have been developed by agronomists and environmental scientists to measure portions of essential nutrients that relate to plant uptake and plant health. Trace element extractions are important in tracking the levels of heavy metals in environmental samples that may be toxic or detrimental to human health. While there are no specific

methods for the sole determination of anthropogenic depositions of elements, the various nutrient availability and toxic element extraction procedures have proven useful in archaeological samples.

Chelates are complex organic molecules that surround and hold metallic ions in solution that would otherwise quickly precipitate. The diethylenetriaminepentaacetic acid (DTPA) chelate extraction method (Lindsay and Norvell 1978) can be used to solubilize surface-adsorbed and slightly soluble trace metals that may be plant available. This method is often used in determining heavy metal contamination of environmental samples, and it is useful in characterizing the metal ions associated with human activities such as food use and mineral use in workshop activities. Dilute acid is also used as an extractant for P, Fe, and heavy metals that are related to ancient activities. Wells (2004) used 1 M HCl extraction of plaza floor samples to study ancient uses at the site of El Coyote in Honduras. Parnell and colleagues (Parnell, Terry, and Golden 2001) compared the results of Classic Maya household floor samples prepared by total digestion (nitric and perchloric acids) with the results of the same samples extracted with Mehlich II for P and DTPA chelate for metals. They reported that the signatures of extractable P and heavy metals were more closely related to cultural deposits than were the total element analyses. They argue that the extraction procedures produced superior results for the interpretation of ancient human activities at Piedras Negras, Guatemala.

Stable carbon isotopes

Carbon, including the heavier isotope of carbon (^{13}C), becomes incorporated and preserved within the soil organic matter or humus as plants decay. Humus molecules are recalcitrant and resist further decomposition to gaseous or soluble compounds. Plant photosynthesis pathways tend to discriminate against the heavier ^{13}C , and therefore plant tissues are depleted in ^{13}C in comparison with the natural abundance of ^{13}C in atmospheric CO_2 . Most plants, including the trees and vines of the forest,

possess a C3 photosynthetic system that is highly discriminatory toward ^{13}C . A few of the tropical grasses (maize, *Zea mays* and sugarcane, *Saccharum* sp.) and certain other plants (e.g., amaranths) possess a more efficient C4 photosynthetic system that is less discriminatory towards the heavier C isotope. For this reason, C4 plant tissues tend to be enriched in ^{13}C compared with the tissues of C3 plants. As the plants die and decompose, portions of both carbon isotopes are incorporated into the recalcitrant humus molecules. Thus, the SOM contains a vegetative history of C3 and C4 vegetation over several centuries. Measurement of the $\delta^{13}\text{C}$ enrichment of the SOM in soils that have lengthy histories of C3 forest vegetation interrupted by periods of clearing for C4 maize agriculture has been used to delineate areas of ancient maize production in the Caribbean islands and in Mesoamerica (Webb, Schwarcz, and Healy 2004; Wright, Terry, and Eberl 2009).

Biomarkers

Biomarkers are described as unique organic molecules produced by specific organisms. These biomarkers may become associated with clay surfaces or are absorbed into humus and thus are preserved for later extraction and measurement. Biomarkers of archaeological significance include the following: animal fats in cooking and dairying residues; plant oils and waxes; and coprostanol and lithocholic acid as indicators of human waste and animal manures, respectively. Plant alkaloids serve as biomarkers of specific plants, for instance: caffeine from coffee, cacao, and a variety of teas; theobromine from cacao; and nicotine from tobacco. Some of these biomarkers have been successfully extracted from pots and potsherds.

Synchrotron-Based X-Ray Analytical Techniques and Materials Analysis

LOÏC BERTRAND

IPANEMA CNRS MIC UVSQ, Université Paris-Saclay, France

Synchrotron radiation is the electromagnetic radiation (photons) emitted tangentially to the path of charged particles—generally electrons, or, more rarely, positrons—accelerated at relativistic energies. The phenomenon was postulated in 1944 by V. Veksler in Russia while independently the future Nobel prize laureate E. M. McMillan constructed the first table-top synchrotron one year later. The synchrotron radiation emission was initially regarded as an undesirable energy loss that has to be compensated at cyclotron-based particle colliders. Synchrotrons are nowadays used as intense and versatile sources of photons for the study of matter. At synchrotron facilities, a pulsed particle beam is accelerated at high energy and stored in a “storage ring.” To produce photons, transverse acceleration of the particle beam is achieved through the application of high magnetic fields generated from permanent magnets or electromagnets along the storage ring. Two main categories of magnetic devices are used: bending magnets (magnetic dipoles) and insertion devices in straight sections, consisting of wigglers (succession of dipoles of inverted polarities) and undulators (wigglers with shorter period that lead to coherent summing up of emitted photon beam amplitudes, providing an extreme brightness to the emitted beam). Since the third generation of synchrotrons, their magnetic lattice is optimized to implement undulators. There are about 60 synchrotrons in operation, of which roughly half are third-generation facilities. The photon beams are operated at beamlines. Each beamline is successively composed of an optics hutch, an experimental hutch, and a control cabin. Large-scale synchrotron facilities

operate several dozens of beamlines in parallel, in distinct analytical modalities. Each synchrotron facility runs in a very extended energy range, conveniently described as a critical energy around which the usable energy domain extends. Apart from a few high-energy and low-energy machines, most recent sources operate in a consensus medium range of 2.5–3.0 GeV, which allows the operation of beamlines from the infrared to the hard X-ray range. Modern sources operate in a top-up mode, where the storage ring is refilled in electrons at a low frequency to maintain within typically 1 percent the fluctuations in intensity of the photon beams produced. The specific characteristics of the photon beams generated, in particular their polychromaticity, high flux, low divergence, and small source size, make them particularly suited for an extended range of spectroscopic (see SPECTROSCOPY) and imaging (see IMAGING) techniques of material characterization, particularly in the X-ray energy domain (Bertrand, Cotte et al. 2012). The tunability of the photon beam energy results from the capability to select a narrow energy band-pass in the white polychromatic photon spectrum generated by the photon source, by using crystal or multilayer monochromators ahead of the experimental endstation. Alternatively, a larger energy band-pass may be used in Fourier transform spectroscopy at some beamlines operating in the infrared or UV range. The extreme brightness of the beams, up to 10 billion greater than that obtained with conventional X-ray sources, makes them highly suited to high signal to noise, raster scanning imaging, and/or fast kinetic analyses. Micro- and nano-beams can be generated through focusing optics (Kirkpatrick-Baez mirrors, compound refractive lenses, capillaries, or Fresnel zone plate).

History

The first application of synchrotron methods to archaeology occurred in 1989, when a

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0565

comparison was reported between the content of Gaulish coins in heavy metals and copper, as established from synchrotron X-ray fluorescence (XRF), and neutron activation analyses. Chemical speciation of archaeological systems using X-ray absorption spectroscopy (XAS) appeared shortly later. In 1995, a team of researchers studied the influence of iron and manganese oxidation states on the color of glasses mimicking mediaeval glasses from northern Europe. They studied the L₃ absorption edges of these transition metals, concluding that there was a strong impact of the ferric ion on the glass color. Two years later, new important steps took place with the first use of synchrotron X-ray diffraction (XRD) and of an X-ray microbeam to characterize archaeological samples. In 1997 a microbeam of a few square micrometers was developed using a purpose-built Bragg-Fresnel multilayer lens; the purpose was to study isolated microinclusions from archaeological iron ingots. Since those first interdisciplinary attempts, a steady growth of the use of synchrotron techniques has been observed for advanced archaeometric investigations. The whole sector of ancient materials has published more than a thousand articles that made use of synchrotron techniques thus far.

Elemental analysis

Synchrotron XRF is a powerful method to identify, colocalize, and estimate concentrations in chemical elements. Energies used for multi-elemental studies are typically in the 17–20 keV range. In such conditions, the information depth may not exceed a few hundreds of micrometers in most materials. Archaeological samples are therefore usually studied in a reflection geometry. In current XRF setups, the detection is usually made with a silicon diode detector oriented at 90° to the incident beam in order to minimize scattering from the sample. Synchrotron XRF can be used for point analyses, in 2D maps, or more exceptionally in 3D (e.g., in confocal imaging). By comparison to XRF analysis, which makes use of laboratory sources (see X-RAY FLUORESCENCE SPECTROMETRY (XRF)), the synchrotron source provides the tunability needed for an optimal selection of the beam energy

and a very high flux useful for the detection of traces. Energy selection allows to selectively excite and/or avoid specific emission lines so as to further improve signal to noise. Synchrotron XRF allows for the trace detection of transition metals, typically at the ppm level in inorganic matrices and in the 10–100 ppb range in organic matrices. Quantification is facilitated by the use of a monochromatic excitation beam; however, it still requires a good a priori knowledge of the local composition of the “matrix,” that is, of the composition of the sample excluding the analyte, which is rarely the case for archaeological materials. Two-dimensional XRF mapping data are therefore exploited with caution, as variations in the signal originate from fluctuations both in the matrix composition and in the analyte concentration. Synchrotron XRF has been used to study the chemical composition of bulk “homogenous” archaeological material (glass, obsidians, precious metals, gems), surface layers, or stratigraphic buildups in cross-sections (metals, paints, ceramics, associated corrosion products, bones and hair cross-sections, otoliths, speleothems, and wood studied in dendrochemistry). Systems that allow the fast raster scanning of entire sample or artifact surfaces, sometimes designated as macro-XRF scanning (MA-XRF), were recently developed.

Speciation and molecular analysis

High-resolution tunability of the incident X-ray energy allows for excitation spectroscopy and imaging methods that are still unattainable with laboratory sources. XAS informs on the chemical environment(s) of a selected element (see X-RAY ABSORPTION SPECTROSCOPY (XAS, EXAFS, XANES)). The XAS signal originating from distinct compounds in the analyzed spot due to the complex and heterogeneous character of most archaeological samples is averaged. Archaeology mostly use XANES, XAS analysis at energies close to the absorption edge of target elements. Fingerprint XANES signals from samples are compared to standards. XANES was used to establish the speciation of transition metals in glasses and pigments for archaeometry and conservation studies. Sulfur K-edge XANES of lazurite was

shown to provide insights into the provenance of lapis lazuli. The formation of lustered ceramics has been studied in several XANES speciation studies. The role of sulfur and iron in the degradation of waterlogged wood from important shipwrecks, such as those of the *Mary Rose* and of the *Vasa*, has also been studied through XANES. Taphonomic impacts were studied on geochemical paleoproxies (e.g., otoliths). A recent development of XAS that is particularly appropriate for heterogeneous archaeological samples is full-field imaging, where a large sample area is simultaneously characterized using an area detector. Full-field XANES allowed the collection of high-resolution images on entire thin sections of Roman sigillata shards. At very low energies, XANES (in this context often called STXM, scanning transmission X-ray microscopy) and X-ray Raman spectroscopy are promising solutions to speciate low-Z elements encountered in archaeology, such as carbonaceous compounds. In the low-energy range, synchrotron FT-IR has been used to characterize archaeological organic compounds. Compared to its laboratory counterpart, synchrotron FT-IR allows greater signal-noise point and raster-scanning experiments owing to the brightness of the beam. Several classes of organic compounds have been studied, in particular organic binders in ancient murals, archaeological hairs, and textiles, waterproofing resins coating archaeological amphorae, ancient poisons, and consolidation products used in conservation treatments. Synchrotron FT-IR has also been used to estimate the level of remineralization in ancient bones. Recently, UV-visible photoluminescence imaging has appeared as a versatile and sensitive probe of organic traces and crystal defects. A fossil metallurgical state was observed in a highly corroded copper-based archaeological artifact, where contrast originates solely from distinct crystal defects in cuprous oxide.

Structural and textural analysis

Synchrotron XRD has mainly been used in archaeology to identify crystalline phases in mixtures (see XRD AND MATERIALS ANALYSIS). The solid sample is illuminated with an X-ray beam in a transmission (if thin enough) or a

reflection geometry. Occasionally, subsamples are powdered and studied in capillaries. The powder diffraction rings are often recorded with a 2D detector and then azimuthally integrated to create a radial profile of the scattering intensity versus the scattering angle 2θ . Each phase gives rise to a series of rings that appear as sharp peaks in the radial profile. This fingerprint is matched with databases to identify the phase. The low divergence of the synchrotron beam allows attaining a high angular resolution that is needed to resolve overlaps between diffraction peaks, especially for samples containing multiple phases. Synchrotron XRD has been used to study pigments from ceramic shards and mural paintings, corrosion products, ancient cosmetics, and paleoenvironmental proxies. Archaeological materials are often “bad” powders that do not offer completely random orientation of crystallites, which makes structural and textural studies complex. The Rietveld analysis is sometimes used to evaluate the relative amounts in distinct phases within a mixture, while the pair-distribution function (PDF) analysis has been occasionally reported to study ill-crystallized samples without long-range order. Small-angle X-ray scattering (SAXS) has been used to investigate the organization and alteration state in samples with mesoscale organization (e.g., fibers or biominerals).

Morphological analysis

Synchrotron microcomputed tomography (μ CT) allows for the virtual 3D reconstruction of a volume from radiographs collected at multiple angles. Unlike in laboratory setups (see X-RAY RADIOGRAPHY AND COMPUTED TOMOGRAPHY), the low divergence of the synchrotron beam, which can be considered as parallel, allows for an exact reconstruction. Typical current scintillator technology, optics, and detectors allow the formation of megapixel images with a micrometer spatial resolution. In conventional high-energy setups, optimal spatial resolutions will be around $0.3\text{ }\mu\text{m}$, while several beamlines allow for nanotomography (currently with voxel sizes of ca. 20 nm), yet on micrometric samples. Measurements are performed with a “white” or “pink” beam (with a large energy band-pass defined

by carefully selected incoming beam filters and scintillator), or with a monochromatic beam. In the latter case, beam hardening, which leads to significant artifacts with laboratory sources, is suppressed. The small synchrotron source size generates phase-contrast effects that enhance the contrast at the boundary of low-contrasting domains (phase-contrast μ CT). Synchrotron μ CT has been used in few archaeology systems, for instance to decipher texts on highly degraded ancient scrolls, to follow the application of consolidation treatments, or to discriminate wood, antler, or paleobotanic remains according to 3D morphological features. A significant development of synchrotron μ CT is expected in archaeology, as has been observed in paleontology.

More generally, novel developments in spectral imaging intimately couple spectroscopic with morphological characterization.

Future directions

Synchrotron instruments and methods are constantly evolving to integrate novel practical and conceptual developments. Some of the major current evolutions regard the expansion of nanoprobe, the development of ultrafast experiments, and the exploitation of the coherence of the synchrotron beam. Future evolutions that are specific to archaeology were reviewed by Bertrand, Cotte et al. (2012), Bertrand, Robinet et al. (2012), and Bertrand et al. (2016). As archaeological materials are often heterogeneous in composition, structure, and morphology, the ongoing surge of spectral imaging modalities is well adapted to comprehensive material characterization. Spectral imaging will likely contribute to a deeper understanding of the variability of material composition and properties. The development of multiscale imaging modalities allows the study of samples or artifacts at their successive length scales, from high-resolution features (mineral grain size or below) to macroscopic levels. Such “high spatial dynamics” may bring a more robust interpretation, which integrates material behavior over larger sample areas. In addition, innovative ways to exploit the coherence of the synchrotron beam lead to many novel imaging methods (e.g., holotomography, ptychography,

coherent diffraction imaging). Although algorithmically complex, these methods provide accurate structural information and discrimination of phases, even with low-contrasting optical indices, at high spatial resolutions. An adverse effect of the high flux used in analysis (greater intensities, smaller footprint of the beams) is the possible occurrence of radiation damage. Practical assessments, instrumental innovation, and theoretical studies are jointly being carried out to monitor and mitigate side effects of irradiation toward better sample integrity and confirmed validity of the analyses performed.

TEM and Archaeological Materials

STEFANO GIALANELLA

University of Trento, Italy

Transmission electron microscopy (TEM) (see TRANSMISSION ELECTRON MICROSCOPY) and related spectroscopy techniques are widely used in materials science, solid-state physics, and biology to investigate morphological, analytical, and structural features of material specimens down to subnanometric spatial resolution. An important obstacle to the use of this otherwise extremely powerful characterization tool may be either the availability of observable electron transparent specimens or the possibility of preparing them successfully. In fact, it is not always possible to achieve electron transparency, possibly starting from a bulk sample, but still retaining the general representative features of the material to be examined. Inorganic materials require thickness below 100 nm; larger thicknesses, up to 1 μm , are generally acceptable in the case of organic and biological materials, exhibiting intrinsically lower absorption coefficients for their lower average atomic numbers. High-quality samples are definitely recommended to obtain satisfactory and reliable results, and are really interesting for relevant materials study. As a counterpart, it is important to highlight that a very limited amount of material is required for TEM investigations and this is to be regarded as a potential benefit in applying this technique to archaeological research. The scarce availability of material samples and the requirement for a moderately invasive approach can both be tackled with a TEM-based approach.

Although not so extensively, TEM has been profitably used for the characterization of several archaeological finds. However, since many archaeological materials are very heterogeneous in nature, the representativeness of the microsamples used in TEM analyses must be validated by other techniques.

This is, for instance, the case with ceramic finds, whose central role in archaeology is universally acknowledged, despite their ubiquitous presence in materials cultures (see CHARACTERIZATION OF CERAMICS). Ceramics usually display a comparatively fine-grained fired-clay matrix, in which different temper grains, on some occasions millimetric in size, are dispersed. A thorough TEM study is capable of providing data concerning different aspects of the ceramic industry, raw materials, and technological aspects. A systematic and in a way paradigmatic investigation on ceramics can be found in Mata, Peacor, and Gallart-Martí (2002), one of the first archaeometric reports on the possibilities of TEM in archaeological ceramic research. Several aspects and features of ancient ceramics and relevant production technologies are effectively examined. Heat alterations and relevant crystallographic transformations of clay materials were examined, concerning their effects on the resulting microstructure. Selected area electron diffraction (SAED) patterns confirmed the partial thermally induced dehydroxylation of the clay minerals. Crystallographic phases pertaining to different clay poly-types, such as smectite, (dehydrated) illite, and muscovite, were identified, mostly on the basis of interlayer spacings. In addition to the residual grains of altered clays, newly formed structures were detected, like pyroxenes. Not all of them were visible in the X-ray diffraction (XRD) patterns acquired on the same materials. This is a valuable aspect of electron diffraction in TEM: to reveal phases with a total volume well below the detectability limits of XRD (i.e., 2–3 vol.%) but which can still be identified from their morphology during TEM observations and fully characterized by local crystallographic analyses.

Amorphous regions featuring SAED patterns with the typical diffuse halo were observed, with subnanometric “bloated pores.” These pores are formed by the trapping in the liquid phase, a precursor of the glassy structure, of gaseous decomposition products, for example, carbon dioxide released by calcite on decomposing into calcium oxide. All these crystallographic features

and specific microstructural details, such as the shape and extension of the shrinkage cracks that form as a result of the release of structural hydroxyl groups, and the texture and location of the phases forming during the firing, are important indicators of the pyrotechnological parameters, including the interval of the firing temperature, the duration of the process, the heating and cooling rates, and the firing atmosphere. In a way, the thorough materials characterization that can be achieved thanks to TEM observations and analyses renders very effective and reliable indeed the usage of the detected phases as “mineralogical thermometers.” From a comparison with equilibrium phase diagrams, “calibrated” with the microstructural and chemical data, a realistic interval for the firing temperatures can indeed be estimated. Very helpful for reliable phase identification is the possibility of measuring the chemical composition of the different regions with a spatial resolution comparable to that of the images. This can be effectively accomplished by energy dispersive X-ray spectroscopy (EDXS). The high spatial resolution of TEM observations and associated spectroscopy analyses afford the possibility of investigating even thin surface layers on ceramics artifacts, like enamels and glazes (Mirguet, Roucau, and Sciau 2009). TEM analyses can provide essential clues for understanding the particular chromatic and aesthetic effects of these surface coatings applied to ceramic artifacts.

Thanks to electron microscopy and XRD analyses, the main features of the glazed surfaces (see NANOARCHAEOLOGY) of fragments from a faience (see GLASS AND FAIENCE) vessel excavated in the site of Deir Alla, Jordan were identified (Groot et al. 2006). The glittering and shiny aspect of the glaze was ascribed to chromite (FeCr_2O_4)-based minerals. Submicrometric grains of chromite acted as heterogeneous nucleation sites for nice spherulitic decorative grains. The identification of chromite in these specimens and the relevant archaeological context, dated to the Late Bronze Age of the Near East, allows pre-dating by more than 1,200 years the first certified use of this mineral in the ceramic industry, which was previously attested only in more recent Roman times.

Metals, namely Cu, Au, Ag, Fe, and Co, may act as chromophoric elements also in bulk glasses and have been indeed used for glass coloring (see GLASS COLOR) since protohistoric times (Angelini

et al. 2004). Metals can be found in the glassy matrix as nanometric clusters. The chromatic effect results from the interplay of the composition and size of these clusters. A remarkable example is provided by the notorious Lycurgus Cup in the British Museum. This is a Late Roman glass vessel, decorated with an openwork showing scenes of the death of Lycurgus, the King of the Edoni. The decoration is carved in the glass body and connected to it by shanks and bridges. Perhaps the most famous aspect of this object is its dichroism. It appears opaque green under reflected light, whereas it turns translucent red when illuminated in transmission. The effect is due to the presence of nanometric metallic particles in the 50- to 100-nm range and it is made of an Ag–Au alloy (68:32 approximate ratio) containing 10 percent copper (Barber and Freestone 1990). These results were obtained from an analytical electron microscopy investigation that revealed also the presence of nanometric NaCl crystal, attributed to the reaction with the outer atmosphere of chlorine residues present in the glass. Interestingly, this result has a diagnostic relevance for the storing and preservation conditions. The presence of nanometric metallic particles induces the iridescent effects displayed by pieces of luster pottery, whose color changes according to the incident angle of the impinging light on their decorated surface (Colomban 2009).

Other intriguing structures have been observed in samples extracted from Damascus ancient blades. These blades feature impressive mechanical properties and very sharp cutting edges, resulting from the peculiar thermo-mechanical treatments employed in their manufacture. These weapons, made of high carbon steel, are characterized by a high surface concentration of cementite (Fe_3C) bands, nicely exploited to obtain magnificent decorative surface patterns. It has been proposed that the blades were forged at high temperatures directly from small steel ingots. The raw materials for this alloy were particular ores from Indian mines, whose progressive supply reduction corresponded with the fading of the relevant bladesmith practice. Other essential ingredients of the blades are wood and leaves from specific vegetal materials: *Cassia auriculata* and *Calotropis gigantea*, respectively, employed as carbon carriers. The interplay among these exotic components and the heavy plastic

deformation associated with forging resulted in the formation of nanostructures: for example, cementite nanowires and carbon nanotubes (CNTs) (Reibold et al. 2006). These structures, in particular CNTs, are nowadays attracting an enormous research interest, for several applications and advanced materials, like polymer matrix composites, reinforced and functionalized with CNTs.

TEM studies have been conducted on ancient pigments based on iron oxides. Several aspects have been investigated and the detailed analyses afforded by this technique have provided unique results, extremely important to understanding materials and decoration techniques employed in ancient times. Analyses carried out on the most famous rock paintings in the Lascaux caves have shown that raw materials were prepared and most likely applied to the vault of the cave using bone tools, particularly reindeer antler (Chadefaux et al. 2008). Bone fragments have been identified also in hematite (Fe_2O_3)-based red pigments coming from a completely different archaeological context: the Epigravettian site of Riparo Dalmeri, a rock-shelter inhabited over a time interval beginning 13,400 BP until 12,900 BP. Still referring to this same site, TEM investigations have demonstrated clearly that some of the red pigments used to decorate calcareous stones with animal and human figures were actually of artificial origin (Gialanella et al. 2011). Indeed, hematite-based red pigments can be obtained by heating up goethite (FeOOH) lumps at moderate temperatures (300°C or so) to induce transformation into hematite through the release of molecules of structural water. The occurrence of the transformation is clearly marked by the evident color change from yellow to red. The high spatial resolution that can be achieved with TEM observations and related spectroscopy tools, like EDXS and specifically electron energy loss spectroscopy (EELS), has been strategic to characterizing the surface darkening and, in general, color alteration (see PIGMENT ALTERATION) induced by the interactions of pigments used in oil painting with pollutants contained in the exposure atmosphere (Casadio et al. 2011). Although these investigations are not strictly related to archaeological studies, but rather to the wider frameworks of heritage studies and art history, still they illustrate how TEM observations

are important tools in the study of art materials, and also for diagnostics and restoration purposes (see ELECTRON MICROSCOPY IN CONSERVATION).

Textiles

MARGARITA GLEBA

University of Cambridge, UK

Introduction

Textiles represent one of the earliest human craft technologies and applied arts, and they have been a fundamental part of subsistence, economy, and exchange (Barber 1991). As such, textiles can tell us about social, chronological, and cultural aspects of past societies, and at the same time give us a unique opportunity to come very close to the individual people in their capacity as both users and makers of textiles. Strictly speaking, a textile is something woven, as the word textile is derived from Latin *texere* (to weave). However, the term is often applied to any flexible material made of interwoven or intertwined fibers. A textile, is not simply a binary system of spun or twisted fibers, but first and foremost a result of complex interactions between resources, technology, and society (Andresson Strand et al. 2010). Knowledge of textiles is thus key to our understanding of a multitude of human issues, being able to tell us about social, chronological, and cultural aspects of past human societies.

Textile use goes back to at least the Paleolithic and is intimately connected with the use of clothes by humans. Nevertheless, DNA study of the evolutionary split between head and body lice concluded that people first began wearing clothes at least 190,000 years ago. Those early garments were most likely made of animal skins and hides, which continued to be used as cloth throughout history and to this day. The use of simple textiles and strings is documented by the so-called Venus figurines of the Upper Paleolithic (i.e., by 27,000 BP).

The earliest direct evidence comes from the Czech site of Pavlov, where imprints of twined fabrics have been found on clay. During the following millennia, the technology spread across Eurasia and with the arrival of humans to the

Americas, throughout North and South America. By the Neolithic period, there is a veritable explosion of textile craft with a variety of techniques present: Direct evidence comes from the Levantine area, Anatolia, and Europe.

How far we can push back textile history has to a large extent been determined by textile preservation. Like all organic materials, textiles are subject to a much more rapid decomposition in comparison to materials such as ceramics, stone, and metal. Nevertheless, textiles survive much more frequently than is commonly believed, and, although unevenly distributed and very dependent on environmental conditions, the quantity of material is constantly increasing, particularly thanks to improved excavation and conservation procedures. Preservation conditions also affect the analytical procedures that can be applied to a particular find. Dry conditions, presence of salt, waterlogging, and temperatures below 0 °C preserve textiles almost unaltered. In contrast, charring and mineralization in the presence of metals (in particular copper and iron) and calcium substantially alter the physical and chemical structure of the organic material.

Whatever the condition of preservation, textile recovery greatly depends on excavation methodology and conservation procedures. Thus, in archaeology, the micro-excavation approach, in which entire blocks of earth containing archaeological material are lifted and brought to the laboratory, where they are then carefully excavated by conservators using special equipment and under controlled conditions, has been especially successful in textile recovery and preservation. Their prompt consolidation, documentation, and conservation, given the usually advanced state of degradation, are then essential.

Textile analysis

While basic structural analysis constitutes standard operating procedure in textile research, within recent decades, textile investigation has been enriched by many new analytical methods

derived from natural sciences which can be used to gain new kinds of information (Good 2001; Andersson et al. 2010). Scientific analytical methods allow us to ask a variety of questions about many different aspects of textiles, in particular:

- What materials were used to make the object (characterization)?
- How was the object made (technology)?
- When was the object made (dating)?
- Where was the object made (provenance)?

Furthermore, scientific analysis of the artifacts is essential in order to understand the ways textiles deteriorate, and to determine the best practice to preserve, conserve, handle, and protect the objects for the benefit of present and future generations.

Textile characterization

Textile quality and appearance are dependent on the materials of which the textile has been made, that is, fiber and dye. By studying fiber on a microscopic level we can come closer to understanding the types of raw material used which varied geographically and chronologically and are also indicative of textile origins. Fiber analysis can furthermore address issues of selective breeding (sheep) and cultivation (flax, cotton), processing of fibers (wool sorting), and their wear, which are essential to the understanding of agriculture, animal husbandry, domestication, and technology.

Fiber identification

The main fibers used until the advent of synthetic organic materials were derived from plants (cellulose based: linen, cotton, ramie) and animals (protein based: wool, silk). The biological source of fibers may be identified by optical or digital microscopy on well-preserved textiles using modern reference materials for comparison (both longitudinal and cross-sections). However, many cellulose-based fibers (flax, hemp, nettle) have very similar morphological characteristics and their identification requires the

use of a polarized light microscope to identify microfibrillar orientation, hemp being z-oriented and flax and nettle being s-oriented. Degraded fibers from archaeological and historical textiles are often more complicated to identify and require more sophisticated methods. The best-available method for fiber identification is currently scanning electron microscopy (Rast-Eicher 2016). In highly degraded textiles, alternative methods of differentiation have been further developed, using synchrotron radiation microbeam diffraction and microfluorescence (Müller et al. 2006).

The new methods of amino acid composition, DNA, and protein analyses are being developed for protein-based fibers and allow animal species identification and possibly even differentiation between breeds of the same species.

DNA analysis is a rapidly developing research field with great potential in archaeology, and new genetic research aims at decoding ancient fibers in archaeological textiles. DNA analysis was used recently to identify flax and hemp in the ropes from Christmas Cave in the Dead Sea area. Besides allowing identification of species, mitochondrial DNA (mtDNA) has been widely used to explore origins of domestic sheep. This work, however, has been done primarily on material extracted from sheep bones recovered from archaeological contexts. Techniques and methods are getting more refined, allowing extraction of minute amounts of DNA, such as present in hair shafts, which can then be replicated. Ancient DNA can shed light on gene function, for example hair color, and DNA extracted from textiles may permit tackling questions dealing with ancient sheep breeds and sheep domestication, and development of silk and cotton (Brandt et al. 2011).

Another method to identify animals to species is proteomics. Analysis of relict proteins has shown that the Salish of west-coast North America made their blankets out of dog hair, interweaving it with goat, and that the woolly dog was superseded by sheep by the late nineteenth century (Solazzo et al. 2011).

Fiber analysis

Fiber investigation, however, is more than just identification of material source. By studying fiber on a microscopic level we can come closer

to understanding issues of selective breeding/cultivation, selection, and processing of fibers, and their wear. These issues are essential to the understanding of ancient agriculture, animal husbandry, domestication, and technology.

Analyses of wool fiber fineness, for example, are used to determine the fleece type of ancient sheep. Assessment of fiber quality is based on the diameter measurement of 100 fibers per thread and statistical analyses resulting in a distribution diagram. Wool contains three parts, differing in structure and size: kemp, hair, and the wool itself. Michael Ryder established an evolutionary scheme for wool development based on fiber diameter measurements. Ryder demonstrated that, over the course of time, selective breeding has produced increasingly finer and more uniform wool. Ryder's model has been adapted in recent investigations to account for the fact that the fiber in a textile is a product of numerous processes: breeding, selection, processing, and finishing. The method also allows distinguishing between sheep wool and goat fiber. A large database of measurements is needed to start identifying clusters of wool quality types, which in conjunction with DNA and protein analysis may provide data on ancient and historical sheep and other animal breeds.

Dye analysis

Addition of color has been an integral part of textile making and has important consequences in pattern design and meaning (Cardon 2007). The identification of active dye components and their combination is key to understanding dyeing technology, exchange, aesthetics, value, and meaning. Before the advent of synthetic dyes in the nineteenth century, all dyes were natural, made from various plants and animals. Dye identification can be significant for tracing the origins of textiles, particularly in combination with fiber analysis, since dyes were generally produced from locally available species. Thus, certain dyes were extremely precious and traded over long distances. In the cases of faded or discolored textiles, the original colors may be identified through dye analysis.

Currently the best method for dye and mordant analysis is high- and ultra-performance

liquid chromatography (HPLC/UPLC) (Vanden Berghe, Gleba, and Mannering 2009). The technique allows the identification of the chemical dye components, but does not always enable determination of the source or the specific hue of the textile, making the analyst's experience very important. Since the sources for dyestuffs are numerous throughout the world, it is important to take into account the archaeobotanical data from the area where the dyed textile has been found. Analysis of large series of samples will permit identification of clusters which can be correlated with fiber, and isotopic and biomolecular data.

Textile dating

An approximate date can be ascribed to many textiles by virtue of art historical comparisons; however, this will always be a subjective opinion that is based upon the experience of the researcher. Other methods of dating are based on context or comparison of the object to similar items found at dated archaeological sites, yet the results are simply *terminus ante quem* as the textile may have been old when it was buried. Furthermore, the traditions of continuity meant that certain technical or artistic features were reproduced virtually unchanged for centuries; thus, one item seemingly identical to another could have been made hundreds of years later or indeed earlier than the "dated" example.

AMS radiocarbon dating

The most consistent way to accurately date fibers has been by using radiocarbon analysis. It is a radiometric dating method that uses the naturally occurring radioisotope carbon-14 (^{14}C) to estimate the age of carbon-bearing (i.e., organic) materials. The accelerator mass spectrometry (AMS) method, developed since the late 1990s, is proving a particularly important dating tool. Textiles made over 500 years ago are especially suitable for ^{14}C dating and may even give more precise dates than other materials (Mannering et al. 2010). Dating a large number of textiles, particularly of a specific type, such as carpets, can help in tracing chronological developments

in techniques and styles. The technique is also important for identification of fakes.

Amino acid dating

Recently, a new method for dating silk was suggested (Moini, Klauenberg, and Ballard 2011). The technique relies on the tendency of amino acids in protein to flip from what is known as a left-handed form known as “L” amino acids, to a mirror-image right-handed version, referred to as “D.” The shift in the orientation of the molecule happens at a steady rate, making it possible to tell how old a silk thread is by looking at the ratio of D to L amino acids. One of the advantages of this method, particularly important in the case of usually very fine silk objects, is that while techniques such as radiocarbon dating require several milligrams of silk for each test, this method needs just one-hundredth that amount. The method is particularly accurate for objects dating within the last 500 years that have not been affected by a burial environment, that is, historical textiles.

Textile provenance

Identifying provenance of artifacts in absolute terms is often difficult if not impossible. This is especially true of textiles, which, made with widespread and long-lasting techniques and materials, may defy typological classification, may lack visible reference to their origin, and, furthermore, were moved and traded over vast distances. An important aspect to understanding archaeological textiles is identifying where they were made, and thus exploring the movements of raw materials and finished artifacts, for what this can tell us about the social, economic, cultural, and technological links between sites and regions.

Strontium (Sr) isotopes

In archaeology, strontium (Sr) isotopes have been widely applied, mainly for the purpose of reconstructing human and animal migration routes in antiquity. Strontium isotopic signatures are conveyed from eroding geological materials through soils and the food chain into the human and animal skeleton, where Sr substitutes for

calcium (Ca). Since the path of the strontium isotope ratio through the food chain is unfractionated, it is possible to apply the method also to animals and plants and hence to their products, in this case fiber and consequently textiles. Strontium isotope ratios have been shown to be a unique indicator for wool fiber provenance in Denmark (Frei et al. 2009). This newly developed methodology using thermal ionization mass spectrometry can either be used independently or as a control for typological and/or technical analysis, although it should be applied with caution in some cases as recent studies indicate that $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of archaeological wool textiles recovered from wet burial environments do not accurately reflect wool provenance even after cleaning (von Holstein et al. 2016).

The results of isotopic tracing analysis must be compared with the local geological environment in order to ascertain if the textile was made of local fiber. Thus, this tracing technique relies on local and regional geological differences of the local rock and soil properties, and precise geological maps are necessary. Ideally, such reconstructions would entail the collection of samples from exposed bedrock, soil, plants, and water, along with small fauna and archaeological human remains from the region. While it is not always possible to delineate precisely the exact geographical provenance, the technique provides a potential method for distinguishing between local and nonlocal origin.

Stable isotopes

Combined carbon, nitrogen, and hydrogen isotopes have only occasionally been used in archaeology to establish geographic origin. They have instead been widely employed to investigate diet. However, there is extensive evidence of these isotopes' geographic variation from analysis of keratin in studies of modern human hair and bird feathers and from food traceability studies.

Gradients in stable isotopes identified in modern studies of European sheep meat and wool have now been successfully applied to medieval archaeological wool samples from Iceland, the United Kingdom, Germany, and Sweden (von Holstein et al. 2016). Analysis has shown that the isotopic composition of wool

and bone collagen samples clustered strongly by settlement, demonstrating the feasibility of provenancing keratin preserved in anoxic water-logged contexts. The same methodology has been applied to silks and could be extended to other animal and vegetable fibers.

Conclusion

Throughout the human past, textile manufacture was practiced at all levels of society and was one of the most labor-intensive of all occupations. As such, it was an industry of great cultural and social importance and should be factored into any balanced assessment of the past. Over the last decades, textile studies have developed into an important new field of archaeological and historical research, largely due to the development of a wide variety of scientific methods that permit their closer characterization, dating, and provenancing. The accumulation of data and the constant improvement and development of analytical techniques are permitting a more synthetic approach to the history of textile art and technology, demonstrating how much we can learn about the culture, society, technology, and economy of the past through textiles.

Volcanic Rock Sourcing

DONATELLA BARCA

University of Calabria, Italy

The issue of volcanic rock sourcing in archaeological research needs to take into account two important factors: the role of lithic raw material in heritage studies and the role of volcanic rocks among different lithic materials.

For the first factor, additional information about the different aspects of past human settlements can be drawn from studies on stone tools. In particular, the latter can highlight the technological and cultural characteristics of a given society, emphasizing its interactions and adaptation to the surrounding environment. The numerous studies on these tools show that the choice of stones was determined not only by the easy access to the source, but also by their features (workability, appearance, color, and so on). For these reasons, the individuation of the exact outcrop or quarry where rocks were sourced by ancient people represents a big challenge. By identifying the provenance of these artifacts, archaeologists can reconstruct the movements of human groups, their management of geographic space, their relations with other neighboring groups, and their access to resources. Moreover, this set of information helps to define the social and economic habits of ancient populations.

The determination of the provenance of archaeological finds is generally possible by comparing their petrographic features (texture and mineral assemblage) and geochemical characteristics (major element and trace element composition) with those of the possible sources of raw material.

In order to compare them, the first step is the collection in the field of samples from the presumed rock source, which has macroscopic features similar to the raw materials of the archaeological finds. The determination of petrographic and geochemical properties of both geological and archaeological samples is the second step.

To identify the geochemical features of the samples, nondestructive analytical techniques are preferred, because they preserve the integrity of the samples. Among these techniques, X-ray fluorescence (XRF) applied in a nondestructive way or portable-XRF (pXRF), proton-induced X-ray emission (PIXE), neutron activation analysis (NAA), and scanning electron microscopy (SEM) are the most effective. In addition, in the past 20 years, laser ablation—inductively coupled—plasma mass spectrometry (LA-ICP-MS), a microdestructive analytical methodology, has also proved to be a powerful tool for in situ determination of trace element patterns in archaeological samples.

As for the second factor mentioned above, among the different types of lithic raw materials employed to produce artifacts, volcanic rocks have always been among the most important and widely used. Volcanic rocks are formed when magma is placed onto the surface of the earth either as coherent lava flows during an effusive eruption or as pyroclastic deposits during an explosive eruption. In relation to the rate of heat loss or cooling, different magmatic fabric can be generated; that is, a magma with a rhyolitic composition can solidify into the following fabrics: phaneritic, aphanitic, glassy vitrophyric, pumiceous, or pyroclastic.

An interesting example of the use of volcanic rocks in sculpture is given by the megalithic Moai statues of Easter Island, Chile (Gioncada et al. 2010). The latter represent the heads and upper bodies of the inhabitants' ancestors which, according to most archaeological interpretations, colonized the island, coming from southeast Polynesia. The stones used to fashion the Moai statues and their topknots are represented by several volcanic rocks characterized by different depositional mechanisms and chemical compositions outcropping across the island. Most of the megalithic statues were made using two types of pyroclastic rocks. Only a few of the Moai were fashioned using lavas of trachytic instead of the tuff. Concerning the pedestals, several types of mafic lavas were used for their building (Gioncada et al. 2010).

Specifically, obsidian is an aphyric/subaphyric volcanic glass, typically black, but also gray-greenish or red-black at times. It has different degrees of transparency from shiny to semi-opaque. Since ancient times, various populations preferred obsidian, not only to produce artistic artifacts, but also to make tools and weapons for

everyday life, because of its attributes of fracture predictability and exceptional cutting-edge quality.

Numerous studies, focusing on the characterization of obsidian, demonstrate that: (1) it geologically outcrops in a limited number of locations; (2) although obsidian composition is

extremely felsic (usually with 70% or more of SiO_2), the different sources are typically differentiated on the basis of chemical compositions: for example, oxide percentages of other major elements (Al_2O_3 , Na_2O , K_2O , and CaO), and the trace and rare earth (RE) elements content. These peculiarities explain why the chemical characterization of archaeological obsidian is typically used for provenance studies.

Two examples are herewith reported, referring to the peri-Tyrrhenian and Mexican areas. Experimental researches indicate that sources

of obsidian in the peri-Tyrrhenian area are only found in a limited number of places: on the islands of Lipari, Pantelleria, Palmarola, and Sardinia (Acquafredda et al. 1999; Barca, De Francesco, and Crisci 2007; De Francesco, Crisci, and Bocci 2008; Tykot 2002) (Figure 1a). From a geochemical point of view, trace and RE element concentrations of these geological sources demonstrate that six or seven compositional groups can be distinguished. In general, many properties, such as alkalinity and the nature of crystallites content, permit the discrimination

of these six or seven groups. However, the concentrations of trace and RE elements are the most effective discriminant factors. The sources of Lipari and Palmarola show an extremely homogeneous trace elements composition within the group and they are easily distinguishable from the others. On the contrary, the Pantelleria obsidian shows great variability within the group, but trace element concentrations are typically different. The obsidians of Monte Arci complex in Sardinia are then subdivided into three or four groups named SA and SB, sometimes subdivided into SB1, SB2, and SC. They show similar trace element compositions, but their differences are relevant enough to separate them (Figure 1b).

The case studies conducted on ancient artifacts from various settlements located in the peri-Thyrrhenian area demonstrate that a comparison of archaeological and geological chemical compositions allows us to assign the provenance of obsidian used for Neolithic artifacts to a definite source.

A different situation can be depicted in Central Mexico, where many obsidian sources have been recovered. In detail, they outcrop in the states of Mexico, Hidalgo, Tlaxcala, and Puebla (Carballo, Carballo, and Neff 2007; Cobean et al. 1991) (Figure 2). Despite the high number of sources outcropping in this area, their geochemical characterization (Cobean et al. 1991) shows that they can be discriminated using the trace and RE element concentrations.

The case study on the provenance of obsidian material recovered in Teotihuacan is very interesting. Teotihuacan was one of the most important cities in ancient Mesoamerica during the Classic Period (200–600 CE). It had the economic and political control of hundreds of communities over a large geographical region. The importance of Teotihuacan was also based on the exploitation of obsidian from two nearby sources—Otumba and Sierra de Pachuca (also known as Sierra de las Navajas)—located respectively 10 and 50 km away from the city (Carballo et al. 2007; Gazzola et al. 2010). In addition, many artifacts were produced and exchanged with the elites of foreign regions to extend the political control over remote territories. Indeed, some obsidian finds show different provenance, that is, Paredón (Puebla) and Zacualtipán (Hidalgo).

Recent studies have shown that in addition to obsidian, Mexican people appreciated other types of volcanic material. Indeed, the Teotihuacans used a pyroclastic deposit made of glass shards of rhyolitic composition as an aggregate in the manufacture of plasters (Barca et al. 2013). The glass shards provenance study turned out to be particularly complex. First, to determine the chemical characteristics of the glass shards spread within plasters, two micro-analytical techniques were used: SEM-EDS to determine the major element composition and LA-ICP-MS to determine the trace element composition including RE elements (Barca et al. 2013).

The comparison between geological and archaeological data, once again, has proved to be decisive. Although two main sources of obsidian, Otumba and Sierra de Pachuca, are located near Teotihuacan, comparison of the results obtained on the glass shards within the plasters with the database of Mexican obsidian (Cobean et al. 1991; Carballo et al. 2007) allowed the identification of the magmatic system of Altotonga, Veracruz as a possible source. These data confirm that a vast amount of foreign raw materials and products arrived in Teotihuacan during the Classic Period, as recently suggested also by Carballo et al. (2007), who pointed out that Teotihuacan had a more complex procurement system for the lithic materials than previously thought.

The results obtained show that people living in the compound of Teopancazco near Ciudadela took shards from a source located 180 km from Teotihuacan. This distance had to be walked, since, in ancient Mesoamerica, neither draft animals nor wheels, and thus no chariot, existed.

An integrated analysis of the evidence from Teopancazco excavations indicates that there was an important link between Teopancazco and the Gulf Coast of Mexico (Manzanilla 2011).

However, the reasons for the use of glass shards as an aggregate material are still unknown. Two hypotheses have been advanced. The first is technological: Perhaps the Teotihuacans had guessed that the use of glass shards made the plasters more resistant. The second is that, perhaps for symbolic reasons, the inhabitants of Teopancazco wanted to build their compound with materials coming from the route they had followed from the Gulf Coast to Teotihuacan, tracing their identity to that distant land.

X-Radiography and Ceramics

INA BERG

University of Manchester, UK

Discovered by Wilhelm Röntgen in 1895, X-radiography was quickly put to use to investigate a multitude of human medical conditions. Soon, its potential for art, archaeology, and geology became apparent, and it was utilized to examine ancient human and animal mummies, metals, ceramics, paper, paintings, and soil (Lang and Middleton 2005). The first applications of X-radiography to ceramics date back to the 1930s and 1940s, but its full potential was only realized in the 1970s when Rye published his seminal work on the fundamental patterns and rules underpinning ceramic X-radiography (Rye 1977, 1981). This work was further expanded on by Carr (1990), Carr and Riddick (1990), and Berg (2008). X-radiography has major contributions to make to our understanding of ceramics. However, it is only one of the many tools that are available to researchers, and it is always recommended that as many techniques are used in conjunction with each other as possible.

X-radiography is a type of electromagnetic radiation that penetrates objects in proportion to the atomic density of the materials and thickness of the object, and captures the outgoing radiation as a grayscale image on a monitor or photographic medium. With the proliferation of digital X-radiography in medical and industrial contexts, it is now easier than ever to gain access to suitable facilities. While industrial facilities provide better-quality X-ray images, medical facilities are ubiquitous, may be portable, often offer good value for money, and are adequate for most research purposes. As each machine is different, researchers will need to experiment first to find the best exposure parameters for the given ceramic assemblage.

The advantages of X-radiography for the study of ceramic objects are manifold: Equipment and

facilities are widely available, the technology is nondestructive, it can be used for both fragments and complete objects, it allows speedy acquisition of images, it provides quick image enhancement with commercially available software and relatively fast interpretation of the image, it offers good value for money, and it can be undertaken on individual objects as well as on large assemblages. The only known disadvantage is that ionizing radiation may change a thermoluminescence (TL) date of the object by up to 20 percent. It is important to note that most of the research has been carried out on pottery. However, the investigatory principles can be applied to any clay object, such as figurines, bricks, or even drainage pipes. X-radiography is most commonly utilized to answer the following research questions:

- identification of the object and its condition;
- identification of the material(s) present;
- identification of manufacturing method(s);
- identification of joins, faults, breaks, repairs, and reuse;
- identification of finishing methods and decoration;
- identification of forgeries.

Of these, scholars working with ceramics are mostly concerned with the identification of manufacturing methods and characterization of the fabric.

It was Rye (1977, 1981) who recognized that different primary forming techniques leave characteristic fingerprints in the clay body that can be made visible through X-rays. Pinching, drawing, coil-building, slab-building, molding, and wheel-throwing differ in the alignment and distribution of inclusions, shape and orientation of voids, evenness and thickness of vessel walls, and the visibility of seams where sections of a pot were joined together. Pinching can be recognized by an alignment of inclusions parallel to the surface, but without a recognizable horizontal or vertical orientation. Drawing orients inclusions weakly vertically when viewed in cross-section and voids appear flattened and

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0611

circular when viewed normally. Coiling results in a preferred horizontal orientation of inclusions and elongated, horizontal voids. Inclusions aligned parallel to the surface but without a predominant orientation is a characteristic pattern of slab-building. Molding produces a parallel but random alignment to the surface. Lastly, inclusions aligned parallel to the surface but set at a diagonal orientation when seen from the front are characteristic of wheel-thrown pots (Rye 1981).

Secondary forming techniques, such as scraping, trimming, smoothing, and adding sections, do not normally interfere with the radiographic visibility of the primary techniques (Berg 2008; Carr 1990). The exceptions are the paddle-and-anvil technique because it applies so much pressure that it obliterates all primary features and results in extreme thinning of vessels which removes all extant features. Secondary forming techniques and surface treatments are therefore best understood through macroscopic analysis.

Investigating forming techniques can lead to exciting discoveries, such as the existence of two distinct manufacturing traditions (Attic and Rhodian) for Aegean Bronze Age transport stirrup jars. Used to transport olive oil, the main distinction lay in the forming of the “fake” spout as either a hollow or solid part of the vessel (Leonard et al. 1993). Vandiver (1987), using the no longer supported xeroradiography, was able to reconstruct the slab-building technique used in the Zagros region of modern-day Iran in around 3000 BCE. By using so-called thick sections (whereby a vessel is cut into vertical slices whose cross-sections are then X-rayed), Vandiver was able to reconstruct the precise shape, size, and sequence with which each slab was applied to form a vessel. Nowadays, this kind of analysis can be undertaken using computed tomography (CT). A major study of Cretan Bronze Age pottery by Berg (2009) illustrated the great variety of forming techniques utilized by ancient potters. It also showed that potters often combined multiple forming techniques on the same vessel, such as a Minoan amphora which was constructed by wheel-throwing, coiling, and drawing. The power of this tool is not limited to pottery. Analysis of clay figurines, for example, has proven very effective in understanding step-by-step how they were constructed.

X-radiographs may be helpful in characterizing ceramic fabrics by determining the size, proportion, type, and general mineralogy of inclusions and/or tempering materials. The technique can only do so when the inclusions or temper have different radio-densities from the clay body which makes them stand out. Based on these differences, scholars have been able to distinguish between classes of minerals, though specific attribution is often problematic when inclusions have similar chemical composition, morphology, and radio-densities. In contrast, organic inclusions often burn out during the kiln firing and leave a recognizable void behind (Carr and Komorowski 1991).

Using X-radiography, Blakeley, Brinkmann, and Vitaliano (1989) were able to divide their sherd assemblage of Pompeian Red Ware successfully into two major fabric groups. The validity of these groups was subsequently confirmed using petrology and chemical analysis. Carr (1990, 1993), in contrast, was interested in understanding whether X-radiography could be used to determine whether body sherds found in close proximity to each other during excavation belonged to the same fabric group and hence possibly the same vessel. X-radiography has the ability also to detect unusual tempering practices or combinations of different clays on the same vessel. Despite its great potential, it is always recommended that petrography and chemical analysis are undertaken alongside.

X-radiography can be used to discover structures hidden inside a complete vessel. One of the very earliest applications of this technique discovered that Peruvian water jugs contained an internally hidden whistling mechanism. Repairs—ancient and modern—are often clearly visible macroscopically. However, where there is doubt, X-radiography will be able to detect them easily if they were undertaken with materials of a different atomic density. An example of a known repair is the insertion of a metal pin into the fake spout of a Bronze Age stirrup jar. Damage incurred during the life history of a ceramic object, such as firing cracks, temperature cracks, or stress breakages, will also be clearly visible in an X-ray.

New technologies such as CT have the potential to supersede X-radiography in archaeology in time because they can offer a 2D and 3D view

of the object at macro- and nanoscale, allowing for quantitative and qualitative analysis of temper and pores/voids. However, the disadvantages are currently too great to establish them as a viable alternative. X-radiography is now almost exclusively digital and much improved in quality. Taking X-rays is quick, inexpensive, and nondestructive, and industrial, medical, or veterinary facilities are abundantly available in most locations across the world or can be brought into museums. The resulting images can be viewed immediately and enhanced quickly, if required, using commonly available software packages requiring minimal training. In contrast, CT scanning necessitates for objects to be brought to the facility (portable machines are available, but prohibitively expensive and large), scanning time is measured in minutes and hours rather than seconds, imaging software is highly specialized, thus requiring extensive training, and processing a single image can take hours.

X-Ray Radiography and Material Analysis

MARIEL ALEJANDRA LÓPEZ

Universidad de Buenos Aires, Argentina

X-ray radiography is an established technique used to obtain images by means of X-rays; the first X-ray images were produced by W. C. Röntgen in 1895. Currently, its importance in the analysis of materials is due to the fact that it is considered to be a non-invasive or non-destructive technique, since the radiation passes through the objects without damaging them. The X-rays make it possible to observe the non-visible structure of certain objects, including features of its interior.

In this sense, it is possible to analyze structural weaknesses, internal deterioration, and production defects, as well as to determine superimposed layers of materials such as, for example, surface coverings or pictorial layers. It is also often possible to evaluate through this technique both the mistakes of the producer of the object, as well as traces of his tools and even signatures or inscriptions, thus allowing us to identify the artist or craftsman, or a certain technological tradition, as well as the structure of the object.

Therefore, X-ray images have been used for more than a century for the preliminary or diagnostic analysis of the internal structure and the techniques used in various heritage objects, including those considered as objects of art and those we identify as archaeological. In addition, for the preservation and restoration of the same, the use of radiographic images is an essential tool to examine previous losses, replacements, and restoration methods that would otherwise not be visible.

X-rays are a high-energy electromagnetic radiation that travels like ordinary light, but has the ability to traverse most objects. The X-ray intensity received by the object depends on the thickness of the object and the density and elemental composition of the material or materials with which that object was produced. Thus, if

one exposes an X-ray sensitive film together with an object to an X-ray transmission, an image of the contour and interior of the object is obtained. The denser areas of the object absorb a greater number of X-rays; therefore, those areas where the film is less exposed are clear.

The equipment used throughout the years, from the end of the nineteenth century to the present, for the examination of heritage objects in general, and archaeology in particular, have been primarily those of medical use, both conventional equipment and those machines used for mammography and/or tomography. Equipment manufactured for quality control of industrial products was then successfully tested. However, it is only after the interest that these experiences with heritage objects have awakened in the industry that, in the last third of the twentieth century, there have also been fixed and mobile equipment specially designed to radiograph art and archaeological objects (e.g., Gilardoni et al. 1994) with the aim of studying objects located in exhibitions, or housed in locations such as site museums (Lang and Middleton 1997).

Along with technological advances, X-ray equipment has become increasingly digital in nature. This has resulted in digital radiography, and digital radiography by luminescence. In general, it can be said that the latter type of radiography is based on the luminescent properties of a phosphor plate, which maintains a latent image after being exposed to X-rays, and then is digitized in the reader module using a system based on a laser beam to form the image matrix as a digital file (Gómez López 2015).

The use of the digital version of the radiographs, instead of analog, meant a new set of aims, objectives and advantages, among which stand out:

- the speed of this technique, enabling greater productivity;
- reduction in the number of erroneous exposures;
- longer shelf-life for image plate (IP) boards;
- improvement in image quality;

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0612

- greater ease of interpretation;
- better storage and reproduction of images;
- reduction in use of harmful chemical materials, as well as costs.

In archaeological sciences, the radiographic technique is considered as a useful tool because it is non-invasive, but it must be used with caution, as in the case of ceramic or textile materials, since once they are exposed to X-rays, they are not fit to be dated by thermoluminescent techniques.

The radiographic technique is applied primarily to human remains, to determine some osteopathy or, for example, to interpret the way in which cranial deformations were performed, among other characteristics. It can also be applied to virtually all types of complete or nearly complete objects, of different materials, which for reasons of preservation cannot be analyzed invasively.

This technique is also applied to fragmentary materials in order to evaluate whether they are fragments from the same archaeological piece (Greene and Hartley 2009). Radiographic techniques have been applied for the preliminary analysis of ceramic and metallic materials, especially when the surface cover or corrosion layer does not allow observation of the production technique.

Radiography is also useful in cases of archaeological materials whose shape has been distorted, such as wooden objects or textiles, clothing and related items (O'Connor and Brooks 2007), or when their parts cannot be understood, as in the case of writings, certain sculptures that may be composed of combinations of different materials, such as wood, metal, and ceramics, or when it is a composite object extracted from an excavation, such as a burial urn soon to be micro-excavated in the laboratory.

Thus radiographic techniques are used in archaeology to visualize procedures and sequences of manufacture or industrial production of an object. But they are also used in the diagnostic stages of conservation or restoration of archaeological objects, allowing characterization of repairs carried out on them in a previous and undocumented way, either executed during its original lifetime of use, or in contemporary contexts. In these latter cases, the radiographic technique often reveals restorations made with materials different from the original, whether

compatible or not, and which have been partially or completely obliterated by surface finishes based more on artistic than archaeological considerations, which are also known as "false historical".

In order to apply a radiographic technique it is essential to possess not only contextual information for the heritage object, but also its thickness along its contour or shape and the basic elements that make up its matter, as well as prior knowledge of how the variables used by the X-ray equipment work: voltage (kV), current (mA), exposure time (t), as well as the distance between the focus and the film (dff) which, under different formats and for each case, depends on the object to be irradiated.

In this last regard, despite the indications given by the specific publications on this subject, it is always necessary to make an adjustment in these variables by considering the parameters established by other authors, together with those resulting from a first experimental test with materials of known composition that act as comparative samples (Chaves Castanedo 2015), in order to establish the best exposure parameters, both for the type of equipment used and the type of object to be irradiated, ultimately to achieve an adequate protocol to follow for future examinations. Some examples of such adjustments can be found in López, Caramés and Acevedo (2010), or in Oliveira et al. (2013).

Once the radiographic images were obtained, traditionally they were analyzed simply by the use of a negatoscope, such as those found in medical offices. Internal details of archaeological pieces could be observed, as well as zones of union of parts, or the use of different techniques of manufacturing or industrial production through the marks left by the instruments used in the operational chain.

Thanks to modern equipment, we can now read the results of X-ray irradiation digitally, either because the images have been scanned or because they are directly delivered in this format. In this way, qualitative analysis can be carried out as before, but including techniques such as manipulating the contrast between the different shades of gray that are observed in the images of the irradiated object. Some quantitative observations can also be made, such as adjusted measurements of some of the inner elements to the pieces, or of density of elements

compared with standardized tables according to the materials analyzed.

Finally, although the first tests with radiographic images of different archaeological materials were often done with medical instruments, currently the main institutes of conservation and restoration, as well as laboratories integrated with the largest museums of art and archaeology of the world, or those dedicated specifically to archaeological sciences in some universities, already own their own equipment. There is even equipment specially designed to be transported to the sites of large heritage objects.

XRD and Materials Analysis

PATRICK SEAN QUINN and
AGNESE BENZONELLI

Institute of Archaeology, University College London,
UK

X-ray diffraction (XRD) is one of several scientific techniques that are applied to the materials analysis and cultural interpretation of inorganic mineralized artifacts such as ceramics, lithics, ores, plaster, faience, pigments, slag, and metal. It can also be used to study crystalline phases in some colored and opaque glasses, as well as being applied to crystalline organic materials such as bone and teeth. The technique is used to characterize and in some cases quantify the mineral constituents of these types of artifacts, which in turn can provide information about their raw material sources. In the case of synthetic materials such as ceramics, plaster, pigments, metals, and slag, XRD data can also be used to investigate their manufacturing technology, use, and alteration. The approach is usually applied alongside other methods of compositional characterization, such as transmitted and reflected light microscopy (see PETROGRAPHY AND CERAMICS), scanning electron microscopy (SEM), and instrumental geochemistry (see X-RAY FLUORESCENCE SPECTROMETRY (XRF), ICP-MS AND MATERIAL ANALYSIS, NEUTRON ACTIVATION ANALYSIS (NAA)). In most cases a small amount of powder is removed from the artifact; however, small objects such as coins can be analyzed nondestructively, by being placed in the diffractometer. This chapter outlines how XRD can be applied to the materials analysis of archaeological ceramics as well as to the study of several other artifact classes mentioned above. For technical details on the technique, see Pollard et al. (2007, 113–16) and Heinmann (2016).

Ancient ceramics are composed of clay minerals, naturally occurring mineral inclusions, and in some cases also mineralized “temper” material,

which is intentionally added. X-ray diffraction can be used to characterize archaeological ceramics in terms of the minerals present and their relative abundance. In this respect it provides data broadly similar to those of thin-section petrography. However, XRD can also be used to identify the minute clay minerals present in low-fired ceramics and the presence of “neo-phases” formed in high-fired specimens. Ceramics are mineralogically complex when compared to other inorganic artifact types and can contain many different mineral species. This can make diffractograms challenging to interpret owing to the presence of multiple peaks, regular overlaps, and large numbers of possible matches (Figure 1a–b). For this reason it is advisable, when characterizing coarse ceramics, to combine XRD with thin-section petrography, particularly if one attempts to generate quantitative data.

Once collected, mineralogical data can be used to classify different archaeological ceramic specimens by detecting similarities and differences between them. This can be done manually or automatically, via multivariate statistics. However, extreme differences in firing conditions can alter the specific mineral assemblages of sherds that were made from identical raw materials (Figure 1a–b). This means that compositional groupings derived from XRD data may reflect both raw materials and technology.

Mineralogical data collected via XRD can be used to interpret the types of raw materials used in the manufacture of ceramics. The presence of specific minerals may be indicative of the use of a particular type of clay deposit (e.g., glauconite forms in shallow marine clay, illite is characteristic of deep-water marine environments). Mineralized temper such as sand or crushed rock may also be used, though distinguishing between this and intrinsic inclusions already present in coarse clay deposits is not possible using XRD alone.

By comparing the mineralogical composition of sherds with potential clay and temper deposits sampled in the field, it may be possible to identify raw material sources used for ceramic manufacture in the past. If it is assumed that clay was not

B: Sample without illite, but with significant quantities of hercynite, which forms above ca. 900 °C. C: Bar diagram of stability of minerals during the firing of ceramics. Abbreviations: Qtz = Quartz; Pl = Plagioclase feldspar; Kfs = Potassium feldspar; Ill = Illite; Chl = Chlorite; Dol = Dolomite; Ca = Calcite; Per = Periclase; Gh = Gehlenite; Di = Diopside; Spl = Spinel; Hem = Hematite. b: Republished with permission of Springer from Travé et al. (2014, fig. 9, p. 399). c: Modified from Maritan et al. (2006, figs. 4 and 5, pp. 6–7).

transported over significant distances, then this can be used to determine production location or “provenance.” X-ray diffraction can play a role in this endeavour, either alone or in combination with other compositional approaches. Statistical classification of XRD data from ceramics and potential raw materials may be used to find possible matches.

The main application of XRD to the materials analysis of archaeological ceramics is in the reconstruction of manufacturing technology. This includes various strands, such as the investigation of paste preparation, the identification of the ingredients used in decorative layers such as slips, paints, and glazes, and the reconstruction of ancient firing temperatures or “archaeothermometry.” The latter has been the subject of numerous studies and is therefore well developed. It relies upon the detection of the presence or absence of a number of indicator minerals that are stable at specific temperatures during the firing of ceramics. As firing temperature increases, certain unstable “primary” mineral phases are lost (e.g., calcite, dolomite, illite) and new stable “firing” minerals will form (e.g., gehlenite, hercynite, mullite, wollastonite; see Figure 1a–b).

The sequence of mineral transformations in ceramics has been investigated experimentally and “bar diagrams” have been proposed (Maggetti 1982; Maritan et al. 2006; see Figure 1b). These can be used to interpret the firing temperatures of sherds from XRD data. It is advisable to refire small fragments of samples at various temperatures and to detect when the original level of firing has been exceeded. The specific transformations occurring in ceramics are dependent on the original composition of the raw clay and any temper, so certain mineral species featured on the bar diagrams (e.g., calcite) or their alteration products (e.g., gehlenite) may not be present. The sequence and level at which mineral alteration takes place are different in oxidizing and reducing firing atmospheres, and the “soaking time” at maximum temperature is also important. This means that the relationship between mineralogy and temperature is not straightforward. The incomplete oxidation of sherds during firing can result in the occurrence of different phases in the core and in the margins of a specimen. For these and other reasons, the

relevance of XRD experiments to archaeological pottery has been questioned.

The mineralogical composition of ceramics can be altered once they have been discarded and buried. Postdepositional alteration can affect adversely the characterization of ceramic raw materials, the interpretation of provenance, and the reconstruction of technology. X-ray diffraction can be used to identify “transformation products,” which can then be taken into account when classifying archaeological pottery and establishing kiln reference groups. Soluble minerals such as calcite, dolomite, and gypsum are particularly susceptible to postdepositional alteration via groundwater, and high-temperature neo-phases, including gehlenite and wollastonite, may be unstable after firing. The sintered clay matrix of ceramics can alter to mixed-layer minerals over time, and hematite may convert to pyrite in anoxic environments such as under the sea.

An important related application of XRD within archaeological materials science is the investigation of natural or artificial pigments used for painting and for decorating ceramics and other artifacts. It can be of help in characterizing the mineral colorant(s) that were used, as well as in studying the weathering and degradation of pigments. For example, the complex manufacturing process of Egyptian blue, which is considered to be the first ever synthetic pigment, was deciphered thanks to data from XRD (Pradell et al. 2006; see Figure 2).

X-ray diffraction is used extensively on metallic artifacts to investigate inlaid decorations made of precious and semiprecious stones, enamel, glass, and niello. The technique is essential for distinguishing, for example, between white inlays made of limestone (calcite) and shell (aragonite), or for identifying the different types of bronze tinning (e.g., Meeks 1986) as well as of niello (e.g., La Niece 1983). It can also be used to study the production of intentional patinas created on metal artifacts for aesthetic purposes and to distinguish this from other types of decoration, or from natural surface corrosion formed over time. Natural and artificial patinas have a different crystal-lattice formation and, as a consequence, exhibit distinctive XRD patterns (Craddock 2009). The study of corrosion layers on metals, glass, and glazes is an important field in archaeological science and conservation studies. The

Figure 2 X-ray diffractogram of synthetic Egyptian blue replica produced with high alkali mixture (3% Na_2O) obtained at a temperature of 1000 °C. Republished with permission of John Wiley & Sons from Pradell et al. (2006, fig. 3, p. 1428).

corrosion patinas on artifact surfaces are made of specific secondary products that reflect the environment in which they were buried and may inform conservation strategies. X-ray diffraction data can be read in combination with “Pourbaix diagrams,” which represent the stability of a metal as a function of potential and pH in an aqueous system. By using XRD it is possible to investigate the composition, morphology, and profile of the corrosion products, which are all essential for understanding the corrosion mechanisms and for developing treatments to prevent or slow down such processes. The most common application has been the study of corrosion products on bronzes, iron, and silver artifacts.

The technique of XRD can be used in the study of slags produced as a by-product of metallurgical processes. It should be carried out in combination with optical examination, in order to ascertain whether the identified phases are residual minerals or newly formed crystals and to assess their distribution in the samples, both of which are essential for technological interpretations. It is also possible to investigate via XRD the material sourcing, provenance, quality, and variability as well as the grade of metalliferous ores.

Despite their mainly amorphous composition, certain glasses and glazes can be studied by XRD. These include those with crystalline opacifiers such as antimonate, as well as colorants such as cuprite. In the investigation of glasses, XRD should be applied alongside complementary techniques such as Raman spectroscopy (see RAMAN SPECTROSCOPY) and SEM.

Important methodological developments that have been applied to the study of archaeological materials include micro-XRD (μXRD) (e.g., Berger et al. 2016) and grazing incidence XRD (GIXRD). The ongoing development of portable XRD (pXRD) devices and the use of a synchrotron source to produce X-rays (SR-XRD) are both likely to have a significant impact in the field of ancient materials characterization and conservation owing to their potential for noninvasive analysis. The latter provides high spatial resolution and high beam intensity.

Analysis of Variance and Covariance

JUAN A. BARCELÓ

Universitat Autònoma de Barcelona, Spain

Variance is the statistical index we use to measure the degree of variation of archaeological magnitudes (length, width, height, weight, volume, perimeter, etc.) or relational index (elongation, shape–form, circularity, concavity, etc.). It should be defined as the expectation of the squared deviation of a random variable from its mean, and it informally measures how far a set of numbers are spread out from their mean. It is calculated by *averaging the squared differences from the mean*:

$$\text{Var}(X) = \frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2$$

where μ represents the mean. However, the variance calculated from the observed archaeological record will in general not match the variance of the original population of artifacts that were produced and used in that place at that moment. Given that the true variance of a population is not known *a priori* and must be computed somehow, we should use an *unbiased sample variance*:

$$s^2 = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2$$

The variance of different variables can be compared to obtain information about how magnitudes vary in different populations. There are two ways of comparing variance. *Covariance* is a measure of the joint variability of two variables, for instance, length (X) and width (Y) measured in a population of stone tools. The sample covariance is defined in terms of the sample means, and it is usually calculated as:

$$\text{cov}(X, Y) = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})$$

For instance, if the stone tools with longer lengths also have greater width, and the same holds for the lesser values, we can say that the covariance between length and width is positive. In the opposite case, when the greater values of one variable mainly correspond to the lesser values of the other (i.e., the variables tend to show opposite behavior), the covariance is negative.

Covariance gives no information about the possible equality of variances. We can test the existence of this circumstance, assuming that when two values are equal, their ratio should be equal to one. In the case of two different populations A and B :

$$H_0 : \frac{s_A^2}{s_B^2} = 1$$

H_0 follows an *F-distribution*—also called Snedecor's distribution—with sample size $(A) - 1$ and sample size $(B) - 1$ degrees of freedom, if the null hypothesis of equality of variances is true. The null hypothesis is rejected if the *F-distribution* value is either too large or too small for the appropriate degrees of freedom.

When comparing the diversity of archaeological material from different assemblages, we are in fact comparing two variables: a magnitude measured for each artifact, or *dependent* variable, and some categories that group the observed artifacts, or the *independent* variable. The dependent variables represent the outcome of human activity in the past, whose variation is being studied. The independent variables represent factors or causes—the potential reasons for variation. For instance, we can analyze the differences in human left femur length in male and female skeletons from an ancient cemetery (Table 1). In this case, the goal is to determine the effects that the biology of sex has on body size.

Alternatively, we can study how ancient huts at different contemporaneous settlements in the same regions show any differences in the degree of curvature of its perimeter (Table 2). The purpose is to determine the effects that the different social or economic functions of each site, or even

Table 1 Measurements of human left femur length (cm) from an ancient cemetery.

Male	Female

49.32	45.9
50.5	47.6
46.7	40.3

the cultural identity of the inhabitants, had on the shape of its buildings.

Instead of a mere variance comparison, we should compare differences among group means and their associated variation within group and between groups. This is usually called *analysis of variance* (ANOVA). In its simplest form, it provides a statistical test of whether or not the means of several groups are equal, and therefore generalizes the Student's *t*-test to more than two groups. ANOVAs are useful for comparing (testing) three or more means (groups or variables) for statistical significance. It is conceptually similar to multiple two-sample *t*-tests, but is more conservative (results in fewer type I errors) and is therefore suited to a wider range of practical problems.

In a one-way analysis of variance, the observed variation is partitioned into components

attributable to different sources of variation. There are two main sources of variation: *between group* and *within group*. It is the same as asking whether the data values within any one settlement or category are all the same, taking into account that there is always some *within-group* variation. In the same way, there may be some *between-group* variation that may affect the general variation among measured data. If different assemblages had different formation processes, or different sites were the consequence of different human activities, such formation processes may have influenced the magnitude we are studying in different ways. Because of sexual dimorphism, femur lengths are different between men and women. If settlements 1–4 were functionally or culturally different, then the size and shape of their buildings would be different. ANOVA tests the non-specific null hypothesis that all four population means are equal.

The between-groups variance can be considered as the variance of the mean from each group or class. It is estimated by:

$$\text{Between-groups variance} = \frac{\sum_g n_g (\bar{x}_g - \bar{x}_T)^2}{g - 1}$$

where n_g is the size of group g , and the means are the mean of each group and the mean of all observations. The between-groups sum of squares has

an associated degree of freedom: the number of groups minus one.

The within-groups variance is derived from the total variance, taking into account the number of groups. This is sometimes called the *error* measurement, and it can be estimated from:

$$\text{Within-groups variance} = \frac{\sum_g \sum_i (x_i - \bar{x}_g)^2}{n - g}$$

where the x_i are those in group g . The within-groups sum of squares has an associated degree of freedom: the total number of values minus the number of groups.

Finally, the test statistic F is computed as:

$$F = \frac{\text{Between-groups variance}}{\text{Within-groups variance}}$$

The probability p of the null hypothesis—all means are equal—is based on the F -distribution with $g-1$ and $n-g$ degrees of freedom.

In the first example, the variation of femur length in males and females, we obtain $F = 10.29$. Given that degrees of freedom are 1 and 8, respectively, the above value of F determines that the null hypothesis—there is no difference between femora from men and women—has a probability of 0.01247. This is a very low value (below the usual threshold of 0.05), so we can conclude that sex (the independent variable) has a significant effect on the length of this bone (the dependent variable), and hence we can conclude there is some sexual dimorphism in this population. In the second example, the variation in house shape from four different sites, we obtain $F = 20.45$. Given that degrees of freedom are 3 and 44, respectively, the above value of F determines that the null hypothesis—there is no difference between buildings in different settlements—has a probability of 0.000. We can conclude that spatial variation at a regional scale (the independent

variable) has a significant effect on the shape of buildings (the dependent variable).

One-way analysis of variance coincides with Student's t -test when the number of groups is two. This can easily be proved in the first example. In the second case, we can obtain further insights into the relationship between the regional differentiation of buildings by comparing the means of houses in each settlement pairwise. This is the basis of the Tuckey post-hoc test to find patterns and/or relationships between subgroups of sampled populations that would otherwise remain undetected and undiscovered with the primary result of the analysis of variance. The procedure calculates for each pair the Studentized range statistic:

$$\frac{\text{Largest mean group} - \text{smallest mean group}}{\text{Standard error of the data}}$$

The Tuckey test is essentially a Student's t -test, except that it corrects for the probability of making one or more false discoveries, or type I errors when performing multiple hypotheses tests. In our second example, the Tuckey post-hoc test gives results as shown in Table 3. This indicates that buildings from Settlement 1 are less circular than buildings from Settlement 2, but they have the same circularity as buildings from Settlements 3 and 4. Buildings from Settlement 2 are different from buildings at any other site. Buildings from Settlement 3 and Settlement 4 are also statistically different.

ANOVA models are parametric, relying on assumptions about the normal distribution of the dependent variables for each level of the independent variable(s). This is a very important aspect because the irregularity of a distribution implies the lack of central tendency, and it prevents the use of the mean as a representative of a group. This assumption is frequently violated in archaeology, given the irregularity and uncontrolled nature of data sampling. The user should check

Table 3 Tuckey post-hoc test results for the data in Table 2.

	Settlement 1	Settlement 2	Settlement 3	Settlement 4
Settlement 1	-	0.000	0.348	0.304
Settlement 2	-	-	0.000	0.000
Settlement 3	-	-	-	0.006
Settlement 4	-	-	-	-

via histograms, skewness and kurtosis tests, overall and for each group. If data are not properly symmetric around the arithmetic mean, one should consider a nonparametric test such as the Kruskal–Wallis test.

Another assumption of this test implies the homogeneity of variances, also called *homoscedasticity*. Its opposite, the non-comparability of variances, is referred to as *heteroscedasticity*. This can be checked via Levene's or Bartlett's tests.

Levene's test is based on the calculation of a test statistic W :

$$W = \frac{N - k}{k - 1} \frac{\sum_{i=1}^k N_i (Z_{i.} - Z_{..})^2}{\sum_{j=1}^k N_i (Z_{ij} - Z_{i.})^2}$$

where k is the number of different groups to which the sampled cases belong, N_i is the number of cases in the i th group, N is the total number of cases in all groups, Z_{ij} is the mean of the i th group, $Z_{i.}$ is the mean of Z_{ij} for the group i , and $Z_{..}$ is the mean of all Z_{ij} .

The test statistic W follows an F -distribution with $k - 1$ and $N - k$ degrees of freedom. If the resulting p -value of Levene's test is less than some significance level (typically 0.05), the null hypothesis of equal variances (homoscedasticity) can be rejected and the conclusions of the analysis of variance are reliable.

An alternative to Levene's test is Bartlett's test. If there are k samples with sizes n_i and s_i^2 sample variances, then Bartlett's test statistic is:

$$\chi^2 = \frac{(N - k) \ln(S_p^2) - \sum_{i=1}^k (n_i - 1) \ln(S_i^2)}{1 + \frac{1}{3(k-1)} \left(\sum_{i=1}^k \left(\frac{1}{n_i - 1} \right) - \frac{1}{N - k} \right)}$$

where N represents the number of observations in all samples and S_p^2 is the pooled estimate for the variance. The test statistic was approximately a χ^2_{k-1} distribution. Thus, the null hypothesis is rejected if $\chi^2 < \chi^2_{k-1, \alpha}$ (where $\chi^2_{k-1, \alpha}$ is the upper tail critical value for the $\chi^2_{k-1, \alpha}$ distribution).

When Levene's or Bartlett's tests show significance, one should switch to more generalized tests, free from homoscedasticity assumptions, and sometimes even nonparametric tests, such as the Kruskal–Wallis test (see below).

Note that the larger the sample size, the more robust ANOVA is to violation of these two

assumptions: normality and homoscedasticity (homogeneity of variance). A sample size > 20 for each level of the independent variable is preferred. For small datasets, instead of using the usual F -distribution, a permutation-calculated p seems less prone to type I errors. A permutation test computes if an F value like the value calculated for the case study may appear in 10,000 repeats of a random set. It is an alternative way to check the probability of accepting or rejecting the null-hypothesis. If the permutation p -value is less than the acceptance level (typically 0.05), we can reject the null hypothesis with confidence.

Therefore, when conducting an ANOVA it is always important to calculate the effect size, because with a big enough sample size, any difference in means, no matter how small, can be statistically significant. The effect size tells the archaeologist the importance of observed differences between assemblages or groups. Omega squared (ω^2) is a measure of effect size, or the degree of association for a population. It is an estimate of how much variance in the dependent variable is accounted for by the independent, and hence explanatory, variable. For between-subjects, fixed effects designs, the formula is:

$$\omega^2 = \frac{F - 1}{F + \frac{N - J + 1}{J - 1}}$$

where N is the sample size, J the number of groups, and F is obtained as a result of ANOVA. ω^2 can have values between ± 1 ; if the observed F is less than 1, ω^2 will be negative. Zero indicates no effect. In our second case, we have obtained $\omega^2 = 0.5486$. According to the standard interpretation by Jacob Cohen, this is a large effect. The opposite, a small effect size, can be inferred when the calculated value of ω^2 is around 0.01.

The Kruskal–Wallis test is the nonparametric equivalent of the one-way analysis of variance (ANOVA), with the data replaced by their ranks. Since it is a nonparametric method, the Kruskal–Wallis test does not assume a normal distribution; it can be regarded as a test of dominance between distributions. The null hypothesis is that the sum of ranks of all groups are equal, and the alternative hypothesis is that at least one summed rank of one group is different from the summed rank of at least one other group. When distributions are similar, medians should

be reported rather than means since they (in the form of mean ranks) are what the test is actually comparing.

The test statistic H is computed as follows. For each group the sum of ranks, R_g , as well as the number of observations, n_g , is obtained, and then:

$$H = \frac{12}{N(N+1)} \sum_{g=1}^g R_g^2/n_g - 3(N+1)$$

where n_g is the number of elements in group g , N is the total number of elements, and R_g is the sum of ranks in group g . The significance level is based on the χ^2 distribution, with $k-1$ degrees of freedom. In our second example, the variation of house shape from four different sites in the same region, the assumption of normality is violated in the case of settlements 1 and 3. The assumption of homoscedasticity is also violated, as suggested by Levene's test (p same variance = 0.0065). Given those violations of initial assumptions, ANOVA results can be suspect. As an alternative, we have performed a Kruskal–Wallis test for the same data: $H = 23.22$, for $4-1$ degrees of freedom, p same sum of ranks = 0.000. We can conclude there is a significant difference between sample medians. Dunn's post-hoc test gives the same results as the Tuckey test for the parametric ANOVA.

In a one-way analysis of variance or a Kruskal–Wallis test we compare a single dependent variable with a single independent variable, composed of any number of different levels. A two-way ANOVA refers to an ANOVA using two independent variables. Expanding the examples above, a two-way ANOVA can examine differences in length (the dependent variable) by activity area (independent variable 1) and time (independent variable 2). Two-way ANOVAs can be used to examine the interaction between the two independent variables. Interactions indicate that differences are not uniform across all categories of the independent variables. For example, stone tools found in long-term residential areas may have smaller lengths overall compared with stone tools from occasional hunting camps, and are longer in the Upper Paleolithic compared with the Mesolithic.

Two-way ANOVAs are also called factorial ANOVAs. Factorial ANOVAs can be balanced (have the same number of observations in each group) or unbalanced (having different numbers

of observations in each group). Unequal sized groups can make it appear that there is an effect when this may not be the case.

Researchers have extended ANOVA as MANOVA and ANCOVA. MANOVA stands for the multivariate analysis of variance. MANOVA is used when there are two or more dependent variables. ANCOVA is the term for analysis of covariance. The ANCOVA is used when the researcher includes one or more covariate variables in the analysis.

Archaeological Classification

DWIGHT W. READ

University of California, Los Angeles, USA

Classification has been crucial to the archaeological enterprise from its inception. Its importance ranges from the pragmatic—a way to arrange artifactual material in an orderly manner—to the analytic—a means to construct a “window” opening onto the lifeway of a past group of people inferred from the traces of their behavior expressed through patterning in artifactual material. From a pragmatic perspective, a classification may be based on the material (see CHROMATOGRAPHY AND ARCHAEOLOGICAL MATERIALS ANALYSIS) from which an artifact is made, its morphological form, its inferred functionality, the technology (see ARCHAEOLOGIES OF TECHNOLOGY) underlying its production, the time period of its occurrence (see DATING IN ARCHAEOLOGY), the cultural context in which it occurs (or is believed to occur), its occurrence together with other artifacts, and so on.

Archaeological classification, in its most basic sense, involves forming classes of artifacts whose members are considered to be equivalent for analytical and interpretive purposes. In this sense, archaeological classification can be thought of as a division of a collection of objects into disjoint and exhaustive classes—an operation known formally as a partition. The rationale for the divisions may range from being empirical, for example when the division is based on properties of the artifacts, to being conceptual, for example when the division is created using constructs developed as part of the archaeologist's understanding of how the material domain integrated with the lifeway of the producers and users of the artifacts that have been recovered.

A classification needs to be rigorous, consistent, and replicable. The choice of one classification over another typically relates to whether the class differences in the selected classification

adequately express the information to be made evident when the classification is used for analytical and other purposes. Under this criterion, using just time-sensitive artifact properties, one might pragmatically construct a chronological classification consisting of a time-ordered (see DATING IN ARCHAEOLOGY) series of artifact classes when the goal is to order sites chronologically by reference to this classification. For a more analytical purpose, such as delineating the presence, form, and importance of social stratification in a past society, the artifact classes might be based on aspects of artifacts pertaining to differences, for example, among social strata.

The multiplicity of possible classifications for the same artifactual material implies the need for criteria that should determine which of several possible classifications may be more appropriate. One such criterion, espoused by William Adams and Ernest Adams (1991), has been to consider that classifications are, essentially, partitions formed pragmatically in accordance with the research interests of the archaeologist. From this perspective, there is no correct classification but only multiple, alternative classifications, each satisfying the partition criterion, and the choice of a particular classification depends on the research goals of the archaeologist.

This pragmatic view of classifications rightly emphasizes that there is no absolute or correct procedure for creating an archaeological classification. Nonetheless, it demotes as incidental to classification the perspective of early twentieth-century archaeologists—from the American Irving Rouse (1939) to the British V. Gordon Childe (1925)—that a classification is not simply a way to order the artifactual material recovered by the archaeologist. It should make evident the cultural context that gave rise to the patterning expressed through a classification. As Robert Dunnell (1971, 132) stated: “*Prehistory assumes that attributes [of artifacts] which are the products of human activity ... can be treated as manifestations of ideas held in common by makers and users of those artifacts*” (emphasis in the original).

Rouse introduced the notion that the ideas held in common by a community of artisans are

DOI: 10.1002/9781119188230.saseas0025

given material form through artifact dimensions, to which he referred as *modes*, and have dimension values or states shared by artisans in their production of artifactual material (see MATERIAL CULTURE). He referred to other artifact dimensions, whose values or states are specific to the individual artisan, as *attributes*. Accordingly, an exhaustive set of artifact dimensions measured over individual artifacts will likely be composed both of modes, on which culturally sensitive classifications are to be based, and of attributes, which represent those aspects of artifacts whose values are specific to the individual artisan. However, which dimensions are modes and which are attributes is not known a priori, and the weakness of this approach to classification has been the lack of a rigorous, objective, and theory-based methodology for distinguishing modes from attributes (but see Read 2007 for such a method). For Childe (1956, 19), the cultural connection is even less detailed and culture (or tradition) is simply the basis for a type: “a type is a type because it is the result of distinct actions all inspired by one and the same tradition.”

Despite not having a satisfactory analytical means for implementing these ideas, the type, perceived as the manifestation of a shared cultural framework, provides, at least conceptually, a way to relate the human modified material remains of a past society to their cultural context. This enables archaeology, as an academic discipline, to position itself as contributing insight, through artifact classification, into the cultural framework of a past society and, by the nature of archaeological material, as introducing a time-depth difficult to obtain through ethnographic fieldwork carried out among living people. The consequence has been that archaeology was seen not just as a historical, but also as an anthropological discipline.

Like the writings of Rouse and Childe, the earlier archaeological literature dealing with classification, especially in North America, was concerned with ways to relate artifactual material to our understanding of human systems. Early to mid-twentieth-century archaeologists who helped frame current-day American archaeological viewpoints regarding artifact classification, such as John Brew, Harry Colton, James Ford, Alfred Vincent Kidder, Alex Krieger, Philip Phillips, Irving Rouse, Albert Spaulding, Jo Ben Wheat, and others, worked from the premise

of classification as a way to make connections between the material properties of artifacts and the concepts and ideas held by their makers and users. As Krieger (1944, 275) put it succinctly, classification provides insight into the “meaning of the myriad works of man.”

One important outcome stemming from this work has been the type-variety system of classification that addressed what had become increasingly evident, especially in American archaeology, namely that the plethora of artifact types being identified as archaeological research became more extensive was not just a sum of independent material instantiations of cultural concepts, but the types often appeared to be linked to one another in the manner of theme and variation. The theme, to use Rouse’s terms, is that of a type defined through modes, variation being represented by alternative forms distinguished through attributes.

The weak point in this view of the role of classification in archaeology has been, and continues to be, its implementation. A crucial difficulty is the double-bind problem that arises from the fact that the means for identifying the cultural dimensions by which the initial heterogeneity in the data brought forward for analysis is to be resolved through classification require already having in hand precisely those cultural dimensions that are to be identified through the classification (Read 2007; 2015). Archaeologists have long recognized that data heterogeneity is problematic; take, for example, the common practice of initially bounding the dataset brought forward for analysis through spatial and temporal boundaries. Creating these boundaries is not done just for analytical convenience, but because of the implicit perception that combining all artifactual material, independently of its spatial and temporal proveniences, into a single dataset leads to analytical obfuscation, not to clarification. Thus, before analysis begins, datasets are circumscribed by reference to spatial and temporal patterns in the data that result from cultural ideas expressed materially through artifacts.

Regardless of theoretical orientation, the general goal of classification is to establish a series of data classes in which the heterogeneity of artifacts in the dataset brought forward for analysis is reexpressed as heterogeneity between internally homogeneous data classes. Through

this transformation, that artifact classes should be culturally valid comes to the fore. Consider that artifacts are initially subdivided according to the kind of material, such as stone, bone, wood, or clay, out of which they have been made or manufactured. Partitioning artifacts by kind of material subdivides the assemblage into artifact classes homogeneous with respect to material and differing among themselves by kind of material. In this manner, the material heterogeneity of individual artifacts is transformed into external class differences among artifact classes that are internally homogeneous (with respect to type of material). The rationale for so doing relates to the fact that the producer's choice of material is not happenstance but reflects cultural (and individual) ideas regarding how the material from which an artifact is made relates to the efficacy with which its intended functionality can be realized. Here functionality may be considered either in its material sense of effectiveness in carrying out a physical task or in its ideational sense of effectiveness in implementing a community-shared cultural ideas system that is expressed, at least in part, through the material properties of artifacts. Artifacts are not made solely in order to carry out material tasks; they are also given particular form and are imbued with properties in order to express ideas and beliefs, hence functionality may be considered ideationally as well as materially. Thus classification connects the cultural domain of concepts and ideas with the material domain of artifacts.

Basing class definitions on the properties of artifacts that reflect the cultural context of the producers gives rise, however, to subjective, extensive definitions that are group-specific, hence spatially and temporally contingent. This subjectivity has led some archaeologists to advocate constructing, in lieu of taxonomies made up of extensive class definitions, paradigmatic classifications based on intentional class definitions expressed through dimension states imposed by the researcher. A paradigmatic classification consists of all possible classes, including vacuous classes, defined through all possible combinations of dimension states, each combination consisting of exactly one state from each dimension. However, for a quantitative variable, the researcher's imposed boundaries for the range of values that define a dimension state introduce subjectivity, unless the imposed widths of boundaries for

the range of values are small in comparison to the scale suitable for expressing numerical variation in a frequency distribution for the mode values through which producers implemented their cultural ideas about artifacts and artifact form. Otherwise, except when there is a uniform distribution, the artifact frequency distribution for the classes of the paradigmatic classification will depend on the choice of the imposed range boundaries used to define the state values for the paradigmatic classification. This means that different boundary choices can change the conclusions drawn from an analysis dependent on those frequencies. It follows that a paradigmatic classification cannot proceed objectively without the double-bind problem of data heterogeneity being solved first; but solving it already produces the basis for a culturally sensitive classification. A means for solving the double-bind problem by recursively identifying homogeneous subsets has been presented by Dwight Read (2007). These homogeneous subsets represent subjective types, not in the sense of distorting subjectivity introduced by the researcher but in the sense of subjectivity introduced through artisan choices in the artisans' production of artifacts. In this manner, objectively determined analytical units suitable for relating the material domain of artifacts, as recovered by the archaeologists, to the ideational domain of past societies, as advocated by the intellectual founders of archaeology, are identified and organized through classifications.

Artificial Intelligence

JUAN A. BARCELÓ

Universitat Autònoma de Barcelona, Spain

Material entities preserved from the past and recognized as cultural assets in the present should be explained by the particular causal structure in which they participated. This cognitive action can be defined in formal terms as the transformation of an incoming sensory vector (the archaeological data) into an appropriate conceptual vector (the explanation), which should be consistent with a hypothetical causal model of the input vector. That is, given a description of archaeologically observable features and a set of already known hypothetical social activities, actions, and/or behavioral models known to the archaeologist, we should assign correct causal explanations to observations (Barceló 2009).

A computer can be programed to carry out this task. The most basic supervised learning algorithms are designed to find a conjunctive description for a single concept *C* that covers positive instances of *C* and that fails to cover negative instances. Thus, we need to determine:

- an initial formulation of a social behavior in the past;
- an object that we know was used in that way, whose visual and nonvisual features have been appropriately quantified;
- an explanation of the association between the behavior and the object (why these particular behavioral mechanics generated the visual/nonvisual appearance of the object);
- some operating criteria;
- a generalization of the object's shape/form that substitutes initial description and is related to the explanation and operating constraints.

In other words, the idea is to program a computer system able to look for common features between positive examples of the known function

to be predicted and common differences between its negative examples. This task is exactly similar to an example of a truth-function learning problem.

In Table 1 the symbol “1” represents a “true” value and the symbol “0” represents a “false” value. Inputs that map onto “true” are treated as positive examples of a particular concept. Inputs that map onto “false” are treated as negative examples (i.e., counter-examples). The process of finding a solution to such a problem is naturally viewed as the process of calculating the *communalities* among positive examples. As such, it is a variation of the philosophical theories seeing *induction* as a process involving the exploitation of similarity. The task of learning possible explanatory functional assignments consists of separating the input vectors, assigning some of them to a known output, from the input vectors that are assigned to one another. We need *training data*, that is, known instances of explanatory concepts, to be capable of predicting the way each explanatory output is connected to each descriptive input.

Basically, this is known as *pattern matching*. Pattern matching is actually a very broad concept. It is useful to distinguish among types of matching. Pattern completion has been defined as the mapping of an incomplete pattern onto a completed version of the same pattern. Pattern transformation is the mapping of one pattern onto a different, related pattern. Pattern association is the arbitrary mapping of one pattern onto another, unrelated pattern. Finally, pattern recognition has been defined as the mapping of a specific pattern onto a more general pattern (that is, the identification of an individual as an exemplar of a class).

A naïve solution would be to list all imaginable “archaeological descriptions” that fit the same “social behavior.” This universal knowledge base would contain all the knowledge needed to “guess” in a rational way the most probable ancient behavior that may have generated the artifact. This way of learning, usually called *case-based learning* in the artificial intelligence literature, is claimed to be a paradigm of the human

way of solving complex diagnostic problems in domains like archaeology.

The trouble is that in most real cases, there are infinite observations that can be causally linked to a single action, making them impossible to list by extension. Added complications arise because archaeological observation and explanation are always fraught with uncertainty. From an analytical perspective, this means that it is quite possible that two similar or even identical samples of prior cases will fall into different classes because there may be ambiguity within the learning sample. If many of our samples are ambiguous for a given set of features, we must conclude that these features have poor explanatory power, and no good solution to the problem may be possible with them alone.

Even the most systematic and long-term record-keeping is unlikely to recover all the possible combinations of values that can arise in human work. Thus, archaeological explanation should be transformed into the task of finding some solution that identifies essential patterns in the samples that are not overly specific to the sample data. There is usually a reduced number of material effects of a past behavior that are individually enough (given the right theoretical assumptions) to infer the presence or absence of such behavior. The trick is finding such material clues of past action, in terms of the perceived modifications caused by the same action, preserved until today. Instead of inferring test implications from a target hypothesis and performing a series of experiments, we should focus our attention on formulating mutually exclusive hypotheses about social action in the past and searching for evidentiary traces in the present to discriminate among them.

Machine learning is a discipline in computer science that has created a number of algorithms to deal with this kind of inductive problems.

The huge number of learning algorithms and data-mining tools make it impossible that we can review the entire field in a single paper (Witten, Frank, and Hall 2011; McCue 2014; Zaki and Meira 2014; Aggarwal 2015). Free computer programs like *Weka* (<http://www.cs.waikato.ac.nz/ml/weka/>, accessed November 24, 2017) and *Tanagra* (<http://eric.univ-lyon2.fr/~ricco/tanagra/en/tanagra.html>, accessed November 24, 2017) can be explored to discover how to extract meaning and knowledge from archaeological data.

The best example of these algorithms is a technique known as “neural network” (Barceló 2009; Krawczak 2013; Keller, Liu, and Fogel 2016). For a computing system to be called an “artificial neural network” or “connectionist system,” it is necessary to have a labeled directed graph structure where nodes (representing artificial neurons) perform some simple computations. These nodes are combined into layers, in such a way that the first layer contains descriptions of archaeological observations converted into vectors. For instance, a vector containing its main measurements can describe a pottery vase: maximum diameter, maximum height, circularity index of the shape contour, convexity index of the shape contour, center of gravity, elongation, 3D sphericity, and so on. A hunting site can be formally described using a numeric vector whose components refer to spatial coordinates, chronology, and abundance of particular archaeological categories (wild fauna bones, arrow points, etc.). The final layer of computing nodes or “neurons” contains the explanation. It can be expressed as a categorical value (this vase was a “jar” or it was not; this vase was an “amphora” or it was not; this site was a “specialized hunting station” or it was not). We can give also a probabilistic context to this “explanatory node,” in such a way that its “degree of activation” represents the confidence we have in this particular explanation.

Different “neurons” from the output or final layer represent different “prototypical values” along an explanatory continuum, and respond with graded signals reflecting how close the current exemplar is to their preferred value. Note that what is really being computed is the degree to which one neuron—representing a microfeature of the final concept or prototype—predicts another neuron or microfeature. Thus, whenever

a certain configuration of input features is present, a certain other set of features is also present. The role of neural networks is to provide general parameterized nonlinear mappings between a visual input, for instance, and a set of output explanatory categories. The neural network builds discriminant functions from its neurons or processing elements. Consequently, the pattern of interconnections between “neurons” is represented mathematically as a weighted, directed graph. In this graph, the vertices or nodes represent the information, the links or edges represent the connections between elements, the weights represent the strengths of these connections, and the directions establish the flow of information and more specifically define inputs and outputs of nodes and of the network. Each node’s activation is based on the activations of the nodes that have connections directed at it, and the weights on those connections. To complete specification of the network, we need to declare how the nodes process information arriving at the incoming links and disseminate the information on the outgoing links.

There are two modes in neural information processing:

- training mode
- using mode.

During training, the network “learns” a nonlinear function, associating outputs (hypothetical explanation) with input patterns from a database of experimental data. The network modifies selectively its parameters, so that application of a set of inputs produces the desired (or at least consistent) set of outputs. Training is accomplished by sequentially applying input vectors—for instance, images or 3D scans—while adjusting network weights according to a predetermined procedure. As the network is trained, the weights of the system are continually adjusted to incrementally reduce the difference between the output of the system (the “automatic” explanation) and the desired response (experimental data). During training, the network weights gradually converge to values such that each input vector produces the desired output vector. The network self-adjusts to produce consistent responses. By adapting its weights, the neural network works towards an

optimal solution based on a measurement of its performance. Once trained, a network’s response becomes insensitive to minor variations in its input.

In the using mode, the presentation of an input sample should trigger the generation of a specific prototype or category. It is clear that a single prototype represents a wide range of quite different possible inputs in that it represents the extended family of relevant features that collectively unite the relevant class of stimuli into a single category. Any member of that diverse class of stimuli will activate the entire prototype. In addition, any other input stimulus that is *similar* to the members of that class, in part or completely, will activate a pattern that is fairly close to the prototype. Consequently, a prototype vector activated by any given visual stimulus will exemplify the accumulated interactions with all the possible sources of the same or similar stimuli in proportion to the frequency with which they have been experienced. A prototype, as formed within a neural network, is by definition “general,” in the same sense in which a property is general: it has many instances, and it can represent a wide range of diverse examples. However, this property does not mean that prototypes are universal generalizations. No prototype feature needs to be universal, or even nearly universal, to all examples in the class.

More than an analogy with a universal database, the basis of artificial intelligence methods is the idea of an *associative memory*. This is a device not only storing associations among individual perceptual representations, but also organizing “conceptual” information not directly derived from the senses. Neural networks are used as associative memories. If the associative mechanism runs properly, then the pattern of activation in the output neurons will be the pattern that was originally associated with the cue pattern. Such an associative memory is not limited to the association of only those specific individual objects whose functional properties have been experimented before. If that was the case, the mechanisms underlying archaeological explanation based on artificial intelligence would be of limited use. As archaeologists, we must identify a range of novel data as corresponding to a given type of object. Generalization is part of our ability to identify objects and events. The

capability for archaeological recognition implies then the existence of some previous form of learning, in which the potentially explanatory categories have been created and defined. The goal of recognition is to perform these identifications correctly, in the sense that identification reflects a meaningful property of the world that is independent of the particular data that are being interpreted. A neural network is a kind of computer program that is able to do the same.

Connectionist systems are not simple mechanisms for recording a set of discrete associative links between elements. The explanatory process is one of getting the computer program to duplicate the specific regularities presented in some specific input. It does this, however, only by constructing a particular dynamical system, whose behavior is defined not only over the set of instances ("associations") to which it has been exposed, but also over the full range of possible input (or hidden) states. That is, a "machine" generating an appropriate response to a certain fixed range of inputs is automatically one that generates *some* response to the full range of possible inputs. It will generate the *correct* response to the full range of possible inputs if the training process succeeds in discovering a distributing transformation from input to internal representations, giving the space of internal representations the right kind of intricate hierarchical structure.

In any case, archaeological explanation cannot be reduced to the task of finding the common structure in a given formalized description, because such methods are limited by the natural grouping of the input data, and they are based on restricting knowledge production to finding literal regularities in the input. Such regularities are not generalizable out of the specific limits of the input data used. Explaining *why* archaeological artifacts and built structures have the shape they have or have been found where they have been found must be grounded in an understanding of both the social and natural events that have influenced the presence/absence, alteration, and displacement of the assemblage as a whole. The fact that the performance of some social action *A*, in circumstances *T*, has a probability *P* of causing a change *Y* in some entity *N* (social agent, community of social agents, or the nature itself) is a property of the social action *A*. It is a measurement of the intensity of the propensity,

tendency, or inclination of certain events to appear in determined causal circumstances. Thus, the primary *explanandum* of archaeological theory is social capacities: the capacity to work, to produce, to exchange, to interact, to obey, or to impose something on someone.

In the same way as human archaeologists, an "intelligent" computer program should understand archaeological observables in terms of a priori *affordances* or *capacities* (Gibson 1987). Aristotle introduced such a concept; he called it *potentiality* (to move, or be movable). For each type of observed change in the materiality of archaeological evidences, a specific type of potentiality should be considered. The implementation of such potentialities inside a machine to explain what it "sees" is usually called computer "simulation" of a causal process (DeLanda 2015; Robinson 2014). It is another domain of artificial intelligence theories, techniques, and technologies.

If machine learning methods like neural networks are just inductive approaches, computer simulation is a deductive approach, whose goal is not the generation of particular explanatory hypotheses but the investigation of the mathematically possible development of specific classes of model systems. A computer simulation is basically the computer representation of a "mechanism," representing how social intentions, goals, and behaviors were causally connected in the past. This can be implemented by building a virtual world, that is, a set of surrogates of people, behavior, objects, and environment placed *within* a computer, and acting according to the implemented mechanism. This is a "generative model," that is, a model of a set of mechanisms. By running such a computer simulation, archaeologists can test the accomplishment a tool or a building had in the past to effectively fulfill a specific action or task, which has been formally described and parameterized; that is to say, whether the object or building was used in a certain way and to satisfy a specific goal.

We can even simulate an entire society in terms of autonomous software entities (the agents) having autonomy and "intelligence" to act like people acted in the past, thus taking their own decisions based on computer instructions that mimic the goals of the humans they "imitate" and the state of the world in which they are supposed to be

(Barceló and Del Castillo 2016). Computationally speaking, virtual agents will consist of a body that contains a set of state variables and behavioral instructions. Social activities will be implemented as simple scripts that are initiated and terminated based on rules. We should also include beliefs and goals—perhaps via the creation and execution of a plan. The attributes and behaviors of agents should be “encapsulated” in the agents themselves, not added later “as an afterthought.” Simulated agents act on the grounds of beliefs about world-states that they contribute to and thus modify, and which will be modified by their actions.

History is then computable to the extent that it can be represented algorithmically as the successive states of some determined input → output function. Such a computable system should consist of a set of states, a set of labels representing the agents and the actions, and a transition relation, prescribing for each state the possible “next steps”—that is, what actions can be performed and (per action) what state results. Selecting one state as the root (the initial state) then yields a formal representation of a process.

The emphasis on computability and algorithms imposed by this “artificial intelligence” approach implies a correlated emphasis in formalization, on objectivity, but not necessary on “truth.” Simulating the past is just a way of increasing the explanatory power of historical explanatory models and not necessarily their “truth likeness.” Each one of the resulting “simulations” of a historical trajectory of events can be used both to experiment with a theory of historical behavior (parameters are manipulated to test for predicted differences) and as a demonstration tool (parameters are manipulated to test for predicted robustness). When used experimentally, manipulations are allowed for agent-level parameters to test the global implications of behavioral assumptions in the case of small-scale societies, but also the computer is allowed to manipulate global parameters to test a macro theory about the dynamical implications of social behavior assumptions in the case of more complex societies. Of course, the limit of the approach is the simple design of the economic behavior, in terms of probabilities for economic success.

Artificial intelligence, virtual reality, and reverse engineering help us to define how ancient

objects, buildings, and landscapes were shaped and used in the past, even if we do not have access to any written description by any contemporaneous witness, starting from the identification of the choices made (among the many possible) in a hypothetical reconstruction of the production process (the *cause*). In this way, we can investigate scientifically and explain to wider audiences the effects of social actions, considering alternative explanatory scenarios, where the parameters of possible behaviors can be changed and tested.

Bayesian Statistics

J. ANDRÉS CHRISTEN

Centro de Investigación en Matemáticas, Mexico

Bayesian statistics is a theory for statistical inference. From particular instances (i.e., data), one may wish to infer general characteristics of the problem being studied. This is a case of inductive logic and is the problem of statistical inference in general. The Bayesian theory, once considered “marginal” or “alternative”, is one of the two mainstream statistical approaches for data analysis (the other being the frequentist or classical approach). As opposed to all other approaches, Bayesian inference is based on a formal mathematical theory that builds an interpretation of probability. Although its origins may be traced back to the eighteenth century, the theory was developed in the twentieth century and became of wide use in the last 20 years with the development of suitable numerical methods and with the ever-increasing availability of computer power. Bayesian statistics has since had a great impact in data analysis in archaeology, and is the only current alternative in many statistical problems.

The problem of statistical inference is a part of the problem of induction, which has been extensively studied in philosophy, particularly in the last century. The epistemological approach of Bayesian inference may be taken as skeptic, as opposed to the rather positivistic perspective of the classical, frequentist, statistical approach. Data is taken to modify a *person's* knowledge regarding some related unknowns. This indeed assumes the existence of *a priori* knowledge of the *person* which, after the evidence provided by data, is transformed into *a posteriori* knowledge. *Person* may refer to a particular human being, but in general refers to any group of people acting together to generate common knowledge, and therefore it is better referred to as an *agent*. An agent may be a person, a public or private organization or, for example, a scientific community.

Inherently, inference brings uncertain statements about the world. Bayesian statistics builds a formal mathematical theory to quantify an agent's uncertainty about formally defined unknowns (namely, alternative models for observables) and, in the presence of data, prescribes how to update the agent's *a priori* information to quantify, *a posteriori*, their uncertainty about the unknowns. The Bayesian theory establishes, under certain general assumptions, that uncertainty should be quantified using probability, and to update such uncertain knowledge one should condition on data, commonly using Bayes theorem. If an agent states that the probability of rain tomorrow is 0.1, they are quantifying the uncertainty of the event *rain tomorrow* (which needs to be properly defined: rain where? how much? etc.).

The traditional definition of probability is based on frequencies. In this perspective, if we toss a coin the probability that it lands on “heads” is 0.5, which means that, if we repeatedly toss the coin, on average it will land on heads 50 percent of the throws. In the long run, when the number of tosses tends to infinity, the proportion of heads over tails should be exactly 0.5. And this is the meaning of “the probability of heads is 0.5”. However, this depends on the availability of a set of identically repeatable events (i.e., the coin tosses), which are at least in principle repeatable an infinite number of times. On the other hand, if an agent says that the probability of rain tomorrow is 0.1, this statement must be interpreted in quite a different manner from the frequentist interpretation of the coin probability, since there is only one “rain tomorrow” (no repeatable events). A frequentist interpretation does not make sense in this case, and note in passing that these sorts of probabilistic statements are far more common, interesting and useful, beyond the idealistic scenario of infinite, identical, repeatable events: the probability that a company goes into default is 0.2, the probability that I die in a car accident is 0.05, and so on.

In contrast, the Bayesian definition of probability, in non-formal terms, may be expressed as follows: an agent quantifies their uncertainty

using probability, which is a formal quantitative representation of their current *opinion* of their uncertainty in a given context that, under certain circumstances, may be turned into a *bet*. That is, if the agent's current probability of rain tomorrow is 0.1, this means that the agent will be prepared to bet at most 9 to 1 against rain tomorrow (the fair odds of probability of 0.1). This also sounds fairly reasonable, if viewed, for example, in the context of probabilities, odds and bets in a horse race. However, this same statement is now currently used in natural and social sciences, as well as in industry and technology, and is based on a skeptic epistemological perspective that inferences are only conditionally bound to an agent's context, current opinion and knowledge, currently available data, and so on, these being "scientific" inferences or otherwise. The probabilistic statements of a Bayesian statistical analysis must be interpreted along such lines.

To fix ideas we now turn to a simple example. Suppose we have a test that will output positive (1) or negative (0) for a particular type of archaeological material. If positive, the material is at least 1,000 years old; if negative it is less than 1,000 years old. The test may yield false positives and false negatives, and an analysis of objects of known ages provides the data in Table 1 for the operating characteristics of the test.

Introducing some notation, let T be the random variable representing the result of the test and E the random variable representing whether the object is more than 1,000 years old ($E=1$) or less than 1,000 years old ($E=0$). Therefore E and T may take the two random values 0 and 1. After performing the test, T may turn out to be positive ($T=1$) or negative ($T=0$), and therefore we may view T as a random variable. However, it seems strange or paradoxical to say that the age of the object is random, for example, stating that $P(E=1)=0.8$, the probability of the object

Table 1 Operating characteristics of the age test example (see text), with 95% of true positives and 90% of true negatives.

	Older than 1,000 years	Younger than 1,000 years
Positive test	95%	10%
Negative test	5%	90%

Table 2 Operating characteristics of the test, as stated in Table 1, now written as conditional probabilities.

	$E=1$	$E=0$
$P(T=1 E)$	0.95	0.1
$P(T=0 E)$	0.05	0.9

being older than 1,000 years is 0.8. Certainly, the object has some well-defined age and it is not the case that it "randomly varies" somehow. But, as explained above, this statement should now be put in a Bayesian perspective: 0.8 quantifies our (we, the agent) uncertainty regarding whether the object is older than 1,000 years and, turning 0.8 into odds, we will be prepared to bet 4 to 1 against it being younger. It now seems clear what we mean, and the "randomness" of E is simply a result of our ignorance regarding the object's age: we, the agent, do not know for sure whether E equals 0 or 1. Introducing more notation, let $P(T=1 | E=1)$ be the probability that $T=1$ given $E=1$, that is, the probability that the test turns out to be positive, provided that the object tested is older than 1,000 years (a true positive). From Table 1, we could assume the conditional probabilities in Table 2.

Now, suppose that for a particular object we perform the mentioned test and it turns out to be positive ($T=1$), what may we say regarding the age of the object? One may be inclined to look at the second column of Table 2 and think that it is "likely" that the object is older than 1,000 years. Should we also consider the third column? That is, how do we formally quantify our uncertainty regarding the age of the object in the light of the positive test result?

Note that Table 2 must have some part of the answer, but it seems to be giving the information backwards. In fact, what we are seeking must be $P(E=1 | T=1)$, that is, *the probability that the object is older than 1,000 years given that the performed test result was positive*. This is the *a posteriori* or posterior probability for $E=1$, after observing a positive test $T=1$. It was assumed that we (the agent) had an *a priori* probability $P(E=1)$ for the object being older than 1,000 years before performing the test.

Let's say, as above, $P(E=1)=0.8$. We need to combine all these pieces of information to

Table 3 Calculations of the posterior probability of the object being older than 1,000 years, $P(E = 1 \mid T = 1)$, using Bayes' theorem. Figures are rounded to four digits.

E	1	0	Addition
$P(E)$ (prior)	0.8	0.2	1.0
$P(T = 1 \mid E)$ (likelihood)	0.95	0.1	
$P(T = 1 \mid E) P(E)$	0.76	0.002	0.762 (= $P(T = 1)$)
$P(E \mid T = 1) = P(T = 1 \mid E)P(E)/P(T = 1)$ (posterior)	0.9974	0.0026	1.0

obtain what is required. Bayes' theorem is precisely the tool for doing that. In its simplest form it reads:

$$P(A|B) = P(B|A)P(A)/P(B)$$

That is, we are able to calculate the probability of event A given B , from the reverse probability of B given A . In fact, Bayes' theorem is sometimes called inverse probability. In terms of our age problem, we may translate it to

$$\begin{aligned} P(E = 1 \mid T = 1) \\ = P(T = 1 \mid E = 1)P(E = 1)/P(T = 1) \end{aligned}$$

and by the law of total probability:

$$\begin{aligned} P(T = 1) &= P(T = 1 \mid E = 1)P(E = 1) \\ &\quad + P(T = 1 \mid E = 0)P(E = 0) \end{aligned}$$

providing a means of calculating the required probability. The involved calculations in our simple example are summarized in Table 3. We can see that the resulting *a posteriori* or posterior probability is $P(E = 1 \mid T = 1) = 0.9974$. Compare this with the *a priori* or prior probability $P(E = 1) = 0.8$. *A priori* we were prepared to bet 4 to 1 against the object being younger than 1,000 years, but now, after the test turned out to be positive, we are prepared to bet 384 to 1. This is the essence of a Bayesian statistical analysis.

Certainly Bayesian analyses in archaeology are far more complex than the above simple example. But they all have these ingredients: (1) a model to construct a likelihood, (2) prior knowledge that is coded into a prior probability distribution, (3) computation of the posterior

distribution using Bayes' theorem, (4) display, use and interpretation of the posterior distribution. All these points may involve different levels of complexity and skills, and in particular (3) is commonly very technical (usually involving sophisticated numerical methods such as MCMC). See Buck and Meson (2015) and references therein as a source of several Bayesian analyses in archaeology.

Chi-Square Analysis

JUAN A. BARCELÓ

Universitat Autònoma de Barcelona, Spain

Chi-square is a statistical test invented by Karl Pearson in 1904 to deal with significant differences in contingency tables. A contingency table is a way of organizing count data in such a way that the frequency distribution of a qualitative variable is tabulated across the frequency distribution of another qualitative variable. Rows represent the different states of one nominal variable, columns represent the states of another nominal variable, and cells contain the integer counts of occurrences of that specific state (row, column) of the two variables. In archaeology, contingency tables are used to compare different assemblages in terms of the frequency different types are represented in each one. The easiest contingency table is a 2×2 tabulation of the quantity of objects of type X at male and female burials.

	<i>Male</i>	<i>Female</i>
Absence of type X	13	10
Presence of type X	5	6

This table indicates that there are 34 single burials: 18 of them contain the buried remains of a male individual and 16 of them the remains of a female individual. In 5 out of 18 male burials an object of type X has been found; in 13 out of 18 male burials archaeologists have not found any object of this kind. It is the same for female burials. As soon as we introduce additional variables (age, kind of burial, etc.), the complexity of the table increases.

Contingency tables can be used to compare the frequency of different kinds of artifacts or ecofacts in different assemblages, activity areas, layers, or even sites. For instance:

	<i>Assemblage</i>				
	<i>1</i>	<i>2</i>	<i>3</i>	<i>4</i>	<i>5</i>
Cattle	20	2	0	0	1
Ovicaprid	0	45	0	0	1
Pig	22	12	0	0	0
Red deer	0	5	6	15	1
Rabbit	0	0	0	0	2
Wild boar	0	4	8	22	1

In this example, we have cross-tabulated two qualitative variables: spatial variation—represented as differentiated assemblages—and animal taxa. It is important to take into account that count data are not the same as frequencies. If assemblages should be compared, then they should be comparable in terms of spatial extension and temporal duration: You cannot compare burials with sites, or garbage pits with the remains of a store. A depot that had a slow and constant formation process of six centuries will have higher numbers of objects than a small depot that accumulated objects during five years. Because you are cross-tabulating “spatial variation” units with another variable (animal or vegetal taxa, artifact type, etc.), spatial units should have the same spatial extension and temporal duration, if the comparison is to have any reliable interpretation. Furthermore, the dependent variable (type, taxa) should be exhaustive and indeterminate attributes must be avoided. You cannot use categories like “other,” “unknown,” “not assigned,” “undetermined,” and so on. A final remark concerning the conversion of count data into frequency distributions is the problem of fragmentation: If you are comparing assemblages in terms of the number of fragments of objects of different kinds, your interpretation will address taphonomic questions (why fragmentation is different at different spatial or temporal units). It would be preferable to use some index estimating the minimum number of complete objects at each assemblage.

Once the contingency table has been built, and the nature of count data has been discussed,

we can calculate a statistical index to discover if both variables are related or not. This index will compare whether the proportions of count data in the different spatiotemporal units (columns) vary significantly between archaeological attributes (rows).

The first step for calculating the statistical test is the calculation of how count data would be distributed among cells if there were no differences between columns and rows. This circumstance is referred to as *statistical independence*. We should calculate the marginal totals, and calculate each cell frequency as the (column total $\times$ row total)/table total:

	Male	Female	Total
Absence of type X	13 [(18 $\times$ 23)/34 = 12.176]	10 [(16 $\times$ 23)/34 = 10.824]	23
Presence of type X	5 [(18 $\times$ 11)/34 = 5.8234]	6 [(16 $\times$ 11)/34 = 5.176]	11
Total	18	16	34

The second step is the calculation of the difference between observed frequencies and expected frequencies, using the cancellation-of-minus-signs property of multiplication, and averaging this difference using the cell expected frequency.

	Male	Female	Total
Absence of type X	$\frac{(13-12.18)^2}{12.18} = 0.055$	$\frac{(10-10.82)^2}{10.82} = 0.06$	23
Presence of type X	$\frac{(5-5.82)^2}{5.82} = 0.12$	$\frac{(6-5.18)^2}{5.18} = 0.13$	11
Total	18	16	34

The chi-square test is calculated by adding all averaged differences: $0.05 + 0.12 + 0.06 + 0.13 = 0.36$. In other words, a chi-square test is calculated following the equation:

$$\chi^2 = \sum \frac{(\text{observed count} - \text{expected count})^2}{\text{expected count}}$$

The result of this calculation is the chi-square test value, and it should be compared with the value you would obtain in the case where the differences between observed and expected would have arisen simply by chance. In the case

of independence, the computed chi-square value should approximate the value of the theoretical chi-square distribution. This is a theoretical probability distribution that has one parameter: k , a positive integer that specifies the number of degrees of freedom—that is, the amount of variation is explained as generated by random variation alone. Because the chi-square test is a summation of values (residuals) for each cell, the higher the number of cells, the higher the number of terms in the summation and the higher the resulting value. The size of the table (number of cells) is the key parameter to estimate the degrees of freedom of the calculated value. We approximate this number by multiplying the number of rows minus 1 by the number of columns minus 1. In this case, this multiplication equals 1: the smallest contingency table.

Years ago, it was necessary to read a table with critical values in theoretical chi-square distribution, organized by degrees of freedom and probability. The user checked for the corresponding value of $(\text{rows} - 1) \times (\text{columns} - 1)$. Nowadays, any specialized software is able to calculate the “probability” of the null hypothesis (“there is no association between both variables”) for the table at hand based on the chi-square distribution with the same degrees of freedom. If data in the table are very unlikely given that the null hypothesis is true, then the null hypothesis should be rejected. If the data are not unlikely, then the null hypothesis is not rejected. If the null hypothesis is rejected, then the result of the test is said to be significant.

Using the free software Past (<https://folk.uio.no/ohammer/past/>), we obtain for the previous example:

Chi squared			
Rows,		Degrees	
columns:	2.2	freedom:	1
Chi²:	0.36583	p (no assoc.):	0.54528
Monte Carlo p:	0.7184		

A null hypothesis of independence (no association) between the presence/absence of type X in male and female burials has a probability of 0.54528. That is, it seems very probable that there are no differences in the proportion of male and female burials with type X objects. The threshold

0.05 is used to decide whether the differences are considered significant or not. P (*no assoc.*) below 0.05 is expected in the case where differences between rows and columns are so great that they are not the consequence of randomness. P values higher than 0.05 indicate that the difference *may* be the result of random variation, and association between type or taxa and location cannot be established with reliability.

For the second example, bones of different animal taxa found in five different assemblages, the table is bigger, with six rows and five columns. Degrees of freedom are calculated as $(6 - 1) \times (5 - 1) = 20$. The chi-square result and its significance for 20 degrees of freedom are as follows:

Chi squared			
Rows,		Degrees	
columns:	6.5	freedom:	20
Chi²:	277.32	p (no assoc.):	3.372E-47
Monte Carlo p:	0.0001		

A null hypothesis of independence (no association) between animal taxa and assemblage location has a very low probability of being true (3.372×10^{-47}). This is a number near 0. That is, differences among the different assemblages in the proportion of animal taxa are too big to have been generated just by random variation, and we can conclude that assemblages are different because of the social activity that generated the deposition of animal bones in them.

This last result can be misleading because the chi-square test has an important limitation: When there are many cells with near-zero expectation, the chi-square test is mostly noise. In our case, the expected values are:

	Assemblage				
	1	2	3	4	5
Cattle	4.76	11.78	1.59	4.19	0.68
Ovicaprid	9.52	23.57	3.17	8.35	1.35
Pig	7.03	17.42	2.34	6.2	1.01
Red deer	5.59	13.83	1.86	4.92	0.8
Rabbit	0.43	1.02	0.14	0.36	0.06
Wild boar	14.7	36.37	4.9	12.94	2.1

It has been shown that 17 out of 30 cells (57%) with expected values less than 5 can result in a loss of statistical power: a tendency not to reject a false null hypothesis (“there is no association between both variables”). The problem with the expected frequencies less than 5 is that the test gives larger values with more frequency than the corresponding chi-square distribution under the null hypothesis. Then we may have overestimation of statistical significance for small data, and potentially important results can be missed.

In the case of fourfold tables (2×2), a chi-square test is inappropriate if the total of the table is less than 20, or if the total lies between 20 and 40 and the smallest expected (not observed) value is less than 5. In contingency tables with more than one degree of freedom, it is inappropriate if more than about one-fifth of the cells have expected values less than 5 or any cell an expected value of less than 1. In those circumstances, *exact* p values can be calculated by simulating very many contingency tables (from 10,000 to 100,000), with the same sample size, and verifying the null hypothesis. Then we repeat the chi-square test for all those simulated cases and count the number of times a value like the one we have calculated for the data may arise under the null hypothesis. This method is called *Monte Carlo simulation*. In our example, Monte Carlo p is higher than the usual asymptotic approximation, but still under the 0.05 threshold, indicating that differences are significant, even in the presence of many expected frequencies under 1.

If calculated p (*no association*) value is less than a chosen threshold for significance level, then we usually reject the null hypothesis—that is, accept that the sample gives reasonable evidence to support the alternative hypothesis: there are differences between assemblages, and hence the archaeological attribute contributes to differentiate spatiotemporal depots. It does *not* imply a “meaningful” or “important” difference; that is for the archaeologist to decide when considering the real-world relevance of the chi-square result. The choice of significance level at which we usually reject the null hypothesis is arbitrary. Most authors refer to statistically significant as $p < 0.05$ and statistically highly significant as $p < 0.001$ (less than one in a thousand chance of being wrong).

There are two types of false conclusions that can be committed when interpreting chi-square test results. They are known as type I error and type II error. A type I error occurs when one concludes that a statistical difference in the proportion of different contents exist between assemblages or spatiotemporal units but this conclusion is empirically wrong. Assuming the null hypothesis is true, the probability of a type I error for any given comparison is the p level. In the vast majority of cases, archaeologists concern themselves with avoiding a type I or alpha error. However, many researchers are unaware that the use of such alpha corrections actually reduces statistical power and increases the likelihood of a type II or beta error (i.e., failing to reject the null hypothesis when the null is false). For instance, consider these two examples:

	Male	Female
Absence of type X	32	28
Presence of type X	17	31

Chi-square test = 3.45; p (no association) = 0.063; Monte Carlo p (no association) = 0.08.

	Male	Female
Absence of type X	5	1
Presence of type X	0	4

Chi-square test = 6.66; p (no association) = 0.009; Monte Carlo p (no association) = 0.04.

In the first case, we cannot reject the null hypothesis, because the probability of committing a type I error is higher than the usual threshold of 0.05. However, the numbers in the table seem to be quite similar, and the probability of the null hypothesis relatively low. Are we incorrectly retaining a false null hypothesis (a “false negative”)? In the second case, differences seem to be clear in the table, but the probability of the null hypothesis is even lower, well below the threshold of statistical significance, and we have no statistical basis for rejecting it, although the sample size is also quite small. Are we incorrectly rejecting a false null hypothesis (a “false positive”)?

The probability of committing a type II error gets smaller as the sample size gets larger. To solve this problem, we have to evaluate the *effect size*, that is, the strength of a phenomenon. Statistical power is a function of three basic factors: the alpha level, sample size, and effect size. In general, larger sample sizes and larger effect sizes lead to greater statistical power. We should be concerned about the relationship between sample size and effect size in determining the statistical power of the association between the two variables.

One of the more popular measures of effect size has been the correlation coefficient. In the chi-square case, a measure of the intensity of association like Cramér’s V can be calculated to guide the user in deciding whether a relationship is important and worth pursuing.

Cramér’s V is computed by taking the square root of the chi-square statistic divided by the sample size and the minimum dimension minus 1:

$$V = \sqrt{\frac{\chi^2}{N \cdot m}}$$

where N is the total number of observations in the table, and m is the minor value of rows – 1 or columns – 1.

Cramér’s V varies between 0 and 1. Close to 0 it shows little association between variables. Close to 1 it indicates a strong association. V values around 1 are expected when there is perfect association. In our examples:

$$V = \sqrt{(3.45/108 \times 1)} = 0.18$$

$$V = \sqrt{(6.6/9 \times 1)} = 0.85$$

Cohen (1988, 25–27, 79–80) provides the following ranges for interpreting the effect sizes in Cramér’s V (depending on the complexity of the contingency table, effect sizes may vary):

Degrees of freedom	Small	Medium	Large
1	0.10	0.30	0.50
2	0.07	0.21	0.35
3	0.06	0.17	0.29
4	0.05	0.15	0.25
5	0.04	0.13	0.22

In the first case, effect size is low-to-medium, and therefore we cannot take a final decision on

gender differentiation based only on available data. In the second case, although the sample size is much smaller, effect size is larger, and the probability of making a type II error diminishes.

Effect size is simply a way of quantifying the size of the difference between two groups. This index emphasizes the size of the difference rather than confounding this with sample size. By placing the emphasis on the most important aspect of the study—the size of the effect—rather than its statistical significance (which conflates effect size and sample size), it suggests a more scientific approach to the accumulation of knowledge. For these reasons, effect size is an important tool in reporting and interpreting the effectiveness of chi-square analysis.

Once we know the actual sample, effect size, and probability of committing a type I error, we can calculate the statistical power of the test using two binomial distributions (Oyeyemi et al. 2010). We can use the G*Power 3 free software (<http://www.gpower.hhu.de/>) (Faul et al. 2007). In the first case, we obtain Power ($1 - \beta$ err prob) = 0.4960273. In the second case, Power ($1 - \beta$ err prob) = 0.4277703. The probability of committing type II errors is relatively high in both cases. Results are suspect, in the first case because the effect size is very low, and in the second case because the sample is too small.

Cluster Analysis

IOULIA PAPAGEORGIOU

Athens University of Economics and Business, Greece

Introduction

Cluster analysis (CA) is a statistical methodology within the area of multivariate statistical analysis (see *MULTIVARIATE ANALYSIS*) mainly used to classify a set of objects into groups based on multiple measurements that are available for each item. The resulting groups, called clusters, are constructed in such a way that similar objects, with respect to their measurements, belong in the same cluster, and dissimilar objects belong to different ones.

Typically, cluster analysis is implemented for a set of objects that is heterogeneous or else comes from different populations, but no previous information about the number of groups or the object membership is available (in contrast, see *SUPERVISED PATTERN RECOGNITION*). The derived clusters will ideally capture the existing heterogeneity, and each cluster will correspond to a subpopulation. If the data set is homogeneous, the methodology will result in a single group.

The need to classify observations of a dataset into groups is essential and applications of CA can be found in almost every scientific area. Clustering can be a part of the exploratory analysis of the data (see *EXPLORATORY DATA ANALYSIS (EDA)*), especially in high dimensional data or large samples. In those cases, the derived smaller number of groups can (1) facilitate summarizing the information included, (2) provide a description of the data at group level, and (3) find patterns or differences among observations. In other cases, clustering is itself the final goal of the analysis.

Scientific topics with significant contributions in the literature are botany, biology, and ecology within the natural sciences area; archaeology, psychology, sociology, criminology, and linguistics within the behavioral and social sciences;

genetics and clinical diagnosis in medicine; pattern recognition and artificial intelligence in engineering and political science; and marketing in information sciences. The numerical methods used for classification appear under different names in the literature, depending on the area of application, for example, taxonomy, segmentation, Q analysis, and unsupervised pattern recognition. Cluster analysis is the generic name that includes all different approaches and techniques aiming to identify the existing subpopulations in a set of objects.

A brief description of each of the main CA approaches is provided in the next section. For a review of techniques, see Cormack (1971) and Baxter (2006).

Typically, CA is implemented in an $n \times p$ matrix of data measurements, where n is the number of objects to be classified and p the number of variables included in the analysis as relevant to the classification criterion. Variables can be continuous or categorical, and most classification techniques can handle mixed type data. Examples of clustering problems in archaeology and variables that may be included in the analysis are:

Example 1. Assume, as the clustering problem, the identification of groups among a set of archaeological findings (e.g., ceramics or glass) based on their chemical composition (see *COMPOSITIONAL DATA ANALYSIS AND POTTERY DATA QUANTIFICATION*). Variables that may be included in the analysis are the measurements of the archaeological findings on selected chemical elements. The derived groups will contain the specimens with similar chemical compositions.

Example 2. Clustering may assist in revealing information on the provenance of marbles used in ancient architecture and sculpture. The selected variables can be geochemical composition (continuous variables) and petrographic analysis consisting of the mineralogical composition of the marbles after microscopic examination. The mineralogical composition variables are categorical and provide

the presence or absence of certain minerals (e.g., dolomite, quartz, and mica), and the levels (low, medium, or high) in the positive case. The resulting groups will represent marbles with similar chemical compositions and petrological properties.

Example 3. To find common authorship among texts, the variables that represent the measurable features of the texts, such as frequency of use of certain words, length of words or sentences, vocabulary, punctuation, and so on, can be included in a cluster analysis. Variables in this example are also of mixed type.

Clustering methodologies and techniques

A wide range of clustering techniques is available in the literature and quite different approaches have been proposed for the problem of CA. Clustering techniques can be categorized into three main classes, in terms of how they try to find the groups in the data: (1) hierarchical clustering; (2) optimization or partitioning; and (3) model-based clustering techniques.

In hierarchical clustering techniques, the process of finding groups in the data consists of an algorithm. The algorithm can initiate from the situation where the n observations form n different clusters and proceed by merging observations or smaller groups in intermediate stages, until all observations are located in one single group. The corresponding methods are called *agglomerative hierarchical clustering methods*, probably the most widely used CA methods in applications. The alternative starting scenario is the reverse, that is, the algorithm initiates from one group which contains all n observations and proceeds by partition of the data into finer groups until the opposite extreme situation, with n single-member groups, is reached. The corresponding methods are called *divisive hierarchical clustering methods*.

In both types of hierarchical clustering, the decision to merge or partition is made based on a proximity measure (see DISTANCE AND DATA TRANSFORMATION) calculated for all possible pairs of objects (observations or groups) at every step of the algorithm. The output of a hierarchical clustering method will provide a sequence of hierarchy in merging or partitioning,

the graphical representation of which is called a *dendrogram*. Figure 1(a and b) shows some typical dendrograms. The proximity (or similarity) measure is defined in association with the type of variable. For continuous interval scale variables, any distance metric can be used as a measure of dissimilarity. The $n \times n$ matrix whose elements are the distances between all possible pairs of observations is called the dissimilarity matrix, usually denoted as D . Denoted by x_{im} , the (i,m) element of the data matrix ($i = 1, 2, \dots, n$, and $m = 1, 2, \dots, p$) and d_{ij} the elements of matrix D , Table 1 lists the most widely used distance metrics as a measure of dissimilarity for continuous variables.

For binary variables or categorical ones with more than two levels, the similarity measures represent the degree of agreement between the two subjects with respect to their answers over the range of categorical variables. Table 2 gives some of the best-known similarity measures—also called similarity coefficients—for a data matrix consisting of p binary variables, where a is the number of variables out of p for which i and j observations occur simultaneously (presence of the particular characteristic), and b , c , and d are the numbers of presence-absence, absence-presence and absence-absence occurrences respectively. For categorical variables with more than two levels, each level is treated as a binary variable. An important distinction, and an issue that needs to be considered before the selection of a similarity measure, is whether the negative (0–0) agreement of two observations in a variable is informative about the association and has to be incorporated in the measure or not. If $s(i, j)$ stands for the similarity measure, the corresponding dissimilarity degree is defined as $d(i, j) = 1 - s(i, j)$.

For ordinal categorical variables, the same measures as in the case of interval scale variables can be used, implemented to the observation ranks r_{im} instead of the observation values x_{im} , $i = 1, 2, \dots, n$ and ($m = 1, 2, \dots, p$). Moreover, the use of

$$Z_{im} = \frac{r_{im} - 1}{M_m - 1}$$

where M_m is the highest rank for each variable m is often used in order to transform the measurements to the (0,1) interval. For ratio variables,

Figure 1 Dendrograms and clusters of pottery data plotted on the first two principal components.

Table 1 Distance measures for continuous variables.

Measure	Definition
Euclidean	$d_{ij} = \sqrt{(x_{i1} - x_{j1})^2 + (x_{i2} - x_{j2})^2 + \dots + (x_{ip} - x_{jp})^2}$
Squared Euclidean	$d_{ij} = (x_{i1} - x_{j1})^2 + (x_{i2} - x_{j2})^2 + \dots + (x_{ip} - x_{jp})^2$
City block or Manhattan	$d_{ij} = x_{i1} - x_{j1} + x_{i2} - x_{j2} + \dots + x_{ip} - x_{jp} $
Minkowski	$d_{ij} = \sqrt[m]{(x_{i1} - x_{j1})^m + (x_{i2} - x_{j2})^m + \dots + (x_{ip} - x_{jp})^m}$
Maximum or Chebyshev	$d_{ij} = \max_k x_{ik} - x_{jk} $
Pearson	$d_{ij} = (1 - \phi_{ij}) / 2$, where ϕ_{ij} is the Pearson correlation between data vectors $\mathbf{x}_i$ and $\mathbf{x}_j$

Table 2 Similarity measures for categorical variables.

Measure	Definition
Simple matching	$s(i, j) = \frac{a + d}{a + b + c + d}$
Jaccard	$s(i, j) = \frac{a}{a + b + c}$
Rogers and Tanimoto	$s(i, j) = \frac{a + d}{a + 2(b + c) + d}$
Anderberg or Sokal and Sneath	$s(i, j) = \frac{a}{a + 2(b + c)}$
Sokal and Sneath	$s(i, j) = \frac{2(a + d)}{2(a + d) + b + c}$
Gower and Legendre	$s(i, j) = \frac{a}{a + 0.5(b + c)}$

a log transformation allows, the measurements to be treated as an interval scale. For mixed type data, where variables of various types are included in the clustering problem, a number of similarity coefficients have been proposed in the literature, with Gower's coefficient the most widely used in practice. The majority of the (dis)similarity measures in Tables 1 and 2 are implemented in standard statistical packages.

Following the choice of the (dis)similarity measure between observations, the second important component in hierarchical clustering is the measure of inter-cluster (dis)similarity, known as linkage. Based on the (dis)similarity measure adopted for observations, linkages determine how this measure will be used in order to define the distance (or similarity) between two groups of observations. This definition will be needed for calculations in all intermediate steps of the hierarchical clustering algorithm. Table 3 lists the most frequently used agglomerative hierarchical linkages.

In conclusion, the main features of hierarchical clustering are that no assumption is made about the distributions of the variables (see NONPARAMETRIC STATISTICS), it is implemented with the help of (dis)similarity measures, the output provides the complete hierarchy in clustering, and any movement (merge or split) at a certain step of the algorithm will not be revised in future steps. Data transformation

(see DISTANCE AND DATA TRANSFORMATION) or different weights per variable during the dis(similarity) measure calculation may also be implemented. Altogether, a wide selection of techniques result as an outcome of all possible combinations of (dis)similarity measures, linkages and, moreover, transformation and weighting. Not all possible clustering techniques produce the same clustering. Their performance depends on the data, how clear the clustering is, the form of the clusters (shape, orientation), the size of the existing groups, and so on. For a more detailed discussion on this topic, we refer to Everitt, Landau, and Leese (2001, chapter 4). An application of hierarchical clustering is provided below.

Optimization or partitioning clustering techniques are characterized as nonhierarchical, and the basic idea behind them is the partition of the observations into groups so that an optimization criterion is accomplished. This criterion attempts to numerically capture the quality of the proposed clustering. Different optimization criteria have been proposed, with the majority of them exploiting—in different ways—the within- and between-cluster measures of dispersion when the observations are allocated into clusters. Let k stands for the number of clusters at a certain step and x'_{ij} is a reallocation of measurements x_{ij} in the data matrix so that i in x'_{ij} stands for the group the observation is assigned to ($i = 1, 2, \dots, k$) and j is the number of the observation in group i , $j = 1, 2, \dots, n_i$, and n_i is the size of group i . If, moreover, $\bar{x}'_i$ stands for the centroid of group i and $\bar{x}$ is the centroid of the complete data, the matrices:

$$W = \frac{1}{n - k} \sum_{i=1}^k \sum_{j=1}^{n_i} (x'_{ij} - \bar{x}'_i) (x'_{ij} - \bar{x}'_i)'$$

$$B = \sum_{i=1}^k n_i (\bar{x}'_i - \bar{x}) (\bar{x}'_i - \bar{x})'$$

denote the matrices of within- and between-clusters dispersion, respectively. The summation $W + B$ is the matrix of total dispersion of the data, which is independent of the specific grouping. The most well-known optimization methods suggested in the literature and used in practice are minimization of $\text{trace}(W)$, minimization

Table 3 Agglomerative linkages.

Linkage	Definition of inter-group distance, d , of groups A and B
Single Linkage or Nearest Neighbor	$d(A, B) = \min_{\substack{i \in A \\ j \in B}} d(i, j)$
Complete Linkage or Furthest Neighbor	$d(A, B) = \max_{\substack{i \in A \\ j \in B}} d(i, j)$
Average Linkage	$d(A, B) = \bar{d}, \text{ where } \bar{d} \text{ is the average distance:}$ $\bar{d} = \frac{1}{n_A n_B} \sum_{i \in A} \sum_{j \in B} d(i, j)$ where n_A, n_B are the group sizes of A and B respectively.
Centroid	$d(A, B) = d(\bar{x}(A) - \bar{x}(B))$ where $\bar{x}(A)$ is the point: $\bar{x}(A) = \frac{1}{n_A} (x_1(A), x_2(A), \dots, x_p(A))$ and is called the centroid of group A.
Ward's	The increase in total error sum of squares (ESS) the merger of A and B will cause. If d_e is the Euclidean distance, the ESS of a group U with centroid $\bar{x}(U)$ is defined as: $\text{ESS}(U) = \sum_{i \in U} d_e(x_i - \bar{x}(U))$

of $\det(W)$, and minimization of $\text{trace}(BW^{-1})$. The method of minimizing the trace of W is not scale-invariant and may impose spherical groups. Minimizing the $\det(W)$ is equivalent to the maximization of the $\det(T)/\det(W)$ criterion. Both methods of minimizing the $\det(W)$ and minimizing the $\text{trace}(BW^{-1})$ are scale-invariant, they may impose the same shape on clusters (although not necessarily spherical), and they also may impose the same number of objects per cluster. For a detailed description, see Everitt et al. (2001, chapter 5) and Baxter (2015, chapter 8). Assuming an optimization criterion, the steps of the algorithm towards the derivation of the “best” clustering are:

- Step 1.* Assume a number of groups k and find an initial partition for the data (it may be derived from a hierarchical method).
- Step 2.* Recalculate the optimization criterion when each observation of a group is located to another.

Step 3. Accept the movement that optimizes the criterion.

The k -means method, probably the most widely used nonhierarchical method, belongs to the same category of clustering methods. It is equivalent to the minimization of $\text{trace}(W)$ method under some regularity conditions.

Model-based CA methods are those where a probability model is assumed for the data, and derivation of the clustering results as a part of the parametric inference of the model (see INFERENCE STATISTICS). More specifically, a finite mixture model (see, among others, McLachlan and Basford 1987) is assumed to describe the data. Each of the existing groups in the data is considered to correspond to one of the mixture components. Mathematically the model is defined as:

$$g(\mathbf{x}; \mathbf{w}, \boldsymbol{\theta}) = \sum_{i=1}^k w_i f_i(\mathbf{x}; \boldsymbol{\theta}_i)$$

where $\mathbf{x}$ is a p -dimensional random vector, f_i the distribution that corresponds to component i

with θ_j their parameter $\theta = (\theta_1, \theta_2, \dots, \theta_k)$ and $w = (w_1, w_2, \dots, w_k)$, the weights of components $\left(\sum_{i=1}^k w_i = 1\right)$.

For the purpose of clustering, the finite mixture model of multivariate normal distribution is frequently used in the case of continuous data. For this instance, $\theta_j = (\mu_j, \Sigma_j)$ where μ_j is the mean vector and Σ_j is the variance-covariance matrix of component j . For any given k , estimating the unknown parameters of the model (see INFERENCE STATISTICS) provides an identification of the distribution components. Each observation is then assigned to a group based on the posterior probabilities calculated for each component distribution. Other distributions besides multivariate normal can also be considered for continuous data, and mixtures of discrete multivariate variables are suitable for categorical data.

The probabilistic approach for CA is (1) computationally demanding, (2) requires hypotheses made about the data and structure of groups, and (3) is more informative with respect to the derived clusters and their properties. Computer and statistical packages are currently available (see below).

Other methods of clustering, such as fuzzy clustering, simulated annealing, self-organizing maps, and so on, are also available (e.g., Baxter 2006).

Application

The dataset chosen for the application consists of chemical measurements of 26 artifacts (pottery) found in four different sites in the United Kingdom (see POTTERY DATA QUANTIFICATION). They form a subset of the data presented in Tubb, Parker, and Nickless (1980), and they are also discussed in Hand et al. (1993). The measurements are available in the “car” (companion to applied regression) R package.

The data matrix is a 26×6 matrix where the first column is a label variable taking four values and indicating the location from which the samples are derived. Analytically the values are: Llanedyrn, Caldicot (two sites near Cardiff; samples 1:16), IsleThorns and AshleyRails (two

sites near the New Forest; samples 17:26). The remaining five columns represent the composition of the samples regarding five chemical elements included in the analysis.

The two geographical locations exhibit great dissimilarity in pottery production, a fact that CA based on measurement of the five chemical elements can reveal. Figures 1a and 1b present the dendrogram of hierarchical CA on standardized data using complete and average linkage respectively. The two geographical locations, as expected, are clearly separated and represented by two distinct clusters according to both linkages. Using principal component analysis (see PRINCIPAL COMPONENT ANALYSIS) for the five chemical elements, a plot in two dimensions of the suggested grouping is possible based on the first two principal components. Figure 1c gives the plot of the resulting grouping after labeling as “1” and “2” the groups with samples from near Cardiff and the New Forest respectively. The difference between the two groups with respect to their chemical composition is apparent. Group 1 from the Cardiff area has negative (standardized) scores in the first principal component, while group 2 has positive scores. Figure 1d is the same but using the samples’ row numbers as labels.

Model-based clustering has also been implemented to data using Fraley and Raftery’s (2002) R package “mclust”. A normal distribution mixture model is fitted and a two-component model is suggested as the best model. The components correspond exactly to the groups obtained from hierarchical methods. More analytically, the best model is the diagonal, varying volume and shape (VVI), that is, the variance-covariance matrices of the two components are diagonal, but not equal.

Compositional Data Analysis

J. BUXEDA I GARRIGÓS

Universitat de Barcelona, Spain

Where the relevant information is not about the amount of each part that is being determined, but about the portion of such a part from the total amount, this is referred to as compositional data. These data naturally arise from a large number of situations in archaeological studies. These deserve particular consideration because most of the statistics are misleading or inapplicable. Determining the chemical composition of an archaeological object is, for example, one of these cases. In this case, analytical techniques (see CHEMISTRY IN ARCHAEOLOGY) are used in order to determine the concentration of an element, or an isotope, in a given sample. This type of analysis enumerates or counts the number of each type of atom in a sample (see MEASUREMENT THEORY). Counting is not expressed in absolute numbers, for example, in the total number of atoms existing in the sample under study. On the contrary, the result is given in relative numbers (usually in % or ppm, parts per million). Thus, 2.50% (in mass %) of Fe is in all cases lower than 5.00%. However, if the first concentration corresponds to the iron content of a Roman amphora, while the second one corresponds to the iron content of a small Roman cup of Terra Sigillata, this might not be the case in absolute amounts (in mass). Considering that a typical amphora weight is around 25 kg, the amount of iron in such an amphora would be 625 g. However, the cup could weigh around 100 g, with an iron content of just 5 g. Thus, when we are interested in compositional data, we are not interested in absolute amounts (i.e., the actual mass). Instead, we are interested in proportions of such amounts (i.e., the relative mass). Similarly, when we are interested in knowing the frequencies of petrographical features (e.g., matrix, pores, inclusions

or different types of inclusions; see OPTICAL MICROSCOPY), the portions of different types or classes of pottery in different assemblages (see ARCHAEOLOGICAL CLASSIFICATION and ASSEMBLAGE), or, when examining forms of objects, differences related to shape regardless of size (see GEOMETRIC MORPHOMETRICS), we are also interested in proportions of the total amount and not in the actual amounts.

Compositional data analysis, dealing with the analysis of portions, encompasses two different geometries that exhibit similar characteristics, but also clear differences. In Figure 1 we can see three different points, $A1 = (16.66, 16.66, 16.66)$, $A2 = (33.33, 33.33, 33.33)$ and $A3 = (66.66, 66.66, 66.66)$, represented in a three-dimensional Euclidean space. Since their coordinates are different, they are placed in different parts of this space and they represent different entities. Each point is expressed as a vector with three real numbers; therefore this space is called a real vector space in three dimensions ($\mathbb{R}^3$). This Euclidean vector space has two basic operations:

- Vector addition: the addition of two vectors $\mathbf{x}$ and $\mathbf{y}$ is the element-wise sum of their values and it corresponds to translation. Thus, our three points $A1$, $A2$ and $A3$ points can be equally displaced two units along the x axis just by adding the vector $\mathbf{u} = (2, 0, 0)$ to them.
- Scalar multiplication: the multiplication of a vector $\mathbf{x}$ by a scalar (a real number) a is the multiplication of its corresponding values by this scalar. The result is a new vector which is a times scaled compared with the original. For example, vector $A2$ is twice vector $A1$, because it is the result of multiplying vector $A1$ by the scalar 2.

The Euclidean vector space is further equipped with the inner product that produces a scalar by adding the result of an element-wise multiplication of two vectors. Let vector $\mathbf{x} = (x_1, x_2, x_3)$ and vector $\mathbf{y} = (y_1, y_2, y_3)$, then $\langle \mathbf{x}, \mathbf{y} \rangle = (x_1 y_1 + x_2 y_2 + x_3 y_3)$ is their inner product. The importance of the inner product is that it induces

Figure 1 Three-dimensional scatterplot showing the points A1, A2 and A3 as representations of the projective point A, and the points B1, B2 and B3 as representations of the projective point B. Two simplices (for $k = 100$ and $k = 200$) are also displayed.

a Euclidean norm and a Euclidean metric. The former is the square root of the inner product of a vector with itself (i.e., $\|\mathbf{x}\| = \langle \mathbf{x}, \mathbf{x} \rangle^{0.5} = (x_1x_1 + x_2x_2 + x_3x_3)^{0.5}$; exponentiation to 0.5 is equivalent to taking the square root). The latter is the norm of the subtraction of two vectors (i.e., $d_{\mathbf{x},\mathbf{y}} = \|\mathbf{x} - \mathbf{y}\| = \langle \mathbf{x} - \mathbf{y}, \mathbf{x} - \mathbf{y} \rangle^{0.5} = ((x_1 - y_1)^2 + (x_2 - y_2)^2 + (x_3 - y_3)^2)^{0.5}$) (see DISTANCE AND DATA TRANSFORMATION). Finally, the inner product also enables us to define the angle between vectors, which is the arccosine of their inner product, divided by the multiplication of their norms. This structure of Euclidean vector space is extended in n -dimensional space (for more than three dimensions) in what is called the Hilbert space, and is the structure that supports most of the statistical methods usually employed. Therefore, statistical methods are usually designed to work with data that can be handled by such a structure (see DESCRIPTIVE STATISTICS; LINEAR MODELS; and MULTIVARIATE ANALYSIS).

If we consider the previous vectors **A1**, **A2** and **A3** from their portions, by dividing the components by their total amounts, we find out that the three of them represent exactly the same values,

that is, the same composition $[0.33, 0.33, 0.33]$. In Figure 1, the three points are on the same line A. They are no more different entities, just different representations of the same point, because what we understand as a line in Euclidean geometry (line A), is just a point in projective geometry (also called an equivalence class). This projective point can then be represented by an infinite number of possible homogeneous coordinates (indicated by the use of square brackets), and this property that all Euclidean points in an equivalence class represent the same composition is called scale-invariance:

$$\begin{aligned} A &= [16.66, 16.66, 16.66] \\ &= [33.33, 33.33, 33.33] \\ &= [66.66, 66.66, 66.66] \end{aligned}$$

In projective geometry, because of the scale-invariance, the previously defined scalar multiplication does not apply: neither the norm nor the Euclidean distance or the translation operation, precluding the use of common statistical techniques on compositional data. Moreover,

these homogeneous coordinates can be dehomogenized by dividing all components by one of them (e.g., $[x_1/x_3, x_2/x_3, x_3/x_3] = [x_1/x_3, x_2/x_3, 1]$). This way, all possible representations of a projective point, or compositional class, produce a unique representation which is called the canonical form. Since all distinct projective points will have the value 1 in the same component, all projective points will be uniquely represented by $(x_1/x_3, x_2/x_3)$ without any loss of information. Because of that, the real projective space has one less dimension ($\mathbb{RP}^2$) than the corresponding real Euclidean space.

Translation of one compositional class to another is performed by the operation called *perturbation* ($\oplus$), that is, by an element-wise multiplication of a given vector by a perturbing one. Let $\mathbf{u} = (2.4, 0.3, 0.3)$, a perturbing vector; $\mathbf{A1} \oplus \mathbf{u} = (16.66 \cdot 2.4, 16.66 \cdot 0.3, 16.66 \cdot 0.3) = (40, 5, 5) = \mathbf{B1}$ (Figure 1); $\mathbf{A2} \oplus \mathbf{u} = (33.33 \cdot 2.4, 33.33 \cdot 0.3, 33.33 \cdot 0.3) = (80, 10, 10) = \mathbf{B2}$; and $\mathbf{A3} \oplus \mathbf{u} = (66.66 \cdot 2.4, 66.66 \cdot 0.3, 66.66 \cdot 0.3) = (160, 20, 20) = \mathbf{B3}$. As in the previous case, $\mathbf{B1}$, $\mathbf{B2}$, and $\mathbf{B3}$, compositionally, are scale-invariant and belong to the same compositional class B (Figure 1). Moreover, perturbing vectors are also scale-invariant, since every compositional class of perturbing vectors will translate some homogeneous coordinates of one compositional class to another. Let $\mathbf{u} = [2.4, 0.3, 0.3]$, a perturbing vector, and a a scalar of value 2; $\mathbf{A1} \oplus a\mathbf{u} = [16.66 \cdot 2 \cdot 2.4, 16.66 \cdot 2 \cdot 0.3, 16.66 \cdot 2 \cdot 0.3] = [80, 10, 10] = \mathbf{B2}$, that is, still some homogeneous coordinates of the compositional class B.

Compositional data analysis also encompasses the geometry of the simplex (S^d). In most circumstances of compositional interest, the data are transformed to some relative values by the closure operation (C), which divides every component by the vector total amount, multiplying the result by an arbitrary constant k (a real number) that will be the new total amount of the vector. Let k be equal to 100 and $\mathbf{A1}$ the homogeneous coordinates; their closure will produce the vector $\mathbf{x}$ in the simplex geometry by:

$$\begin{aligned} \mathbf{A1} \in \mathbb{RP}^2 &\rightarrow \mathbf{x} \\ &= [(100 \cdot 16.66)/(16.66 + 16.66 + 16.66), \\ &\quad (100 \cdot 16.66)/(16.66 + 16.66 + 16.66), \\ &\quad (100 \cdot 16.66)/(16.66 + 16.66 + 16.66)] \\ &= [33.33, 33.33, 33.33] \in S^2 \end{aligned}$$

The result is a representation of this compositional class in relative frequencies (in percentages) in the simplex, which is the smallest part of the original Euclidean space $\mathbb{R}^3$ that would contain all possible points expressed as percentages. For a three-dimensional real Euclidean space, it is the two-dimensional triangle whose vertices lie on the value k of the original axes (i.e., the commonly used ternary diagram). In Figure 1, it is the leftmost simplex, but, for example, a second simplex is shown to the right corresponding to a k of 200.

The properties of the simplex are similar to the real projective space and also preclude the use of the operations and properties of the real Euclidean space. There are also significant differences between both geometries. Some of them arise because, in the simplex, after a perturbation, a new closure is again performed to keep the total amount of the perturbed vector as k . Thus, the position of the point can never be interpreted in terms of the real Euclidean space because it depends on the arbitrary constant k . While homogeneous coordinates representing projective points can still be analyzed as vectors in real Euclidean space, if amounts are considered relevant, this cannot be done with vectors of relative values in the simplex. Besides, in the simplex, it is not possible to evaluate translation beyond the perturbation class. For example, let $\mathbf{x}_0 = [50, 25, 25]$, a composition at time 0, and $\mathbf{x}_1 = [60, 20, 20]$ at time 2; the translation from the former to the latter can be explained by the perturbing vector $\mathbf{u} = [1.2, 0.8, 0.8]$, where the first component has increased, and the other two have decreased. But it could also be explained by $\mathbf{u} = [1.5, 1, 1]$, without any change in the second and third components, or by $\mathbf{u} = [1, 0.6667, 0.6667]$, with changes just in those components. Without further information, one cannot decide which perturbing vector participated, beyond the general information on perturbation class.

All chemical data are given as relative vectors in the simplex. We rarely have any information on the absolute amounts. Moreover, chemical data can be expressed in atomic percentages or in mass, both as elements or as oxides. Those different representations that can be modeled as perturbations should provide, in compositional data analysis, the same results, that is, the analysis

should be invariant regardless of how the data have been reported (i.e., perturbation invariant).

Aitchison's (1986) seminal work on compositional data analysis tried to solve the unit-sum constraint in vectors of relative values in the simplex, the spurious correlation and the negative bias of the variance–covariance. Aitchison identified the simplex as the sample space, presented the operations of perturbation and powering (equivalent to the scalar multiplication in real Euclidean space), and developed the variation matrix that completely determines the covariance structure of compositional data. Aitchison proposed two transformations of the $d+1$ -parts vector of relative values in the simplex that should enable the use of common statistical techniques:

- the additive logratio transformation (alr) $\mathbf{x} \in S^d \rightarrow \mathbf{y} = \log(\mathbf{x}_d/\mathbf{x}_{d+1}) \in \mathbb{R}^d$
- the centered logratio transformation (clr) $\mathbf{x} \in S^d \rightarrow \mathbf{z} = \log(\mathbf{x}/g(\mathbf{x})) \in \mathbb{H} \subset \mathbb{R}^{d+1}$

where $\mathbf{x}_d = [x_1, \dots, x_d]$, $g(\mathbf{x})$ is the geometric mean of all $d+1$ components of $\mathbf{x}$, and $\mathbb{H} \subset \mathbb{R}^{d+1}$ is a hyperplane vector subspace of $\mathbb{R}^{d+1}$. Finally, Aitchison demonstrated that this approach was also scale-invariant, permutation-invariant and subcompositionally coherent. The latter is of critical interest because usually not all components are considered (e.g., only a subset of chemical elements is determined).

Compositional data analysis has seen rapid development in recent years, with very significant contributions. In archaeological sciences, Aitchison's work was first echoed by Baxter (1989), and perturbation was used to model changes in compositions due to loss on ignition, tempering and, especially, weathering (see DETERIORATION; Buxeda i Garrigós 1999). A few years later, it was demonstrated that the simplex is a vector space once the inner product, norm and metric of the Euclidean vector space are adapted to the alr or clr transformed data (Pawlowsky-Glahn and Egozcue 2001; Billheimer, Guttorp, and Fagan 2001). Afterwards, working with coordinates with the isometric logratio transformations (ilr) and the sequential binary partitions (or balances) became an essential new development in compositional data analysis (Pawlowsky-Glahn 2003). Such a development solved part of the problems

associated with the alr and clr transformations, by providing coordinates in a real Euclidean vector space (or Hilbert space). These developments provide a mathematically well-founded method that enables application of all common statistical techniques to compositional data, by using variously transformed data (alr, clr or ilr) as appropriate (Martín-Fernández, Buxeda i Garrigós, and Pawlowsky-Glahn 2015). Moreover, comprehensive software packages have been developed to complement the already existing techniques and software when analyzing compositional data (van de Boogaart and Tolosana-Delgado 2013). Thus, the number of different applications is growing fast, and the ongoing development of an algebra and calculus for compositional data announces even more significant and deep changes in the near future (Pawlowsky-Glahn and Buccianti 2011).

Computer Applications in Archaeology

JEREMY HUGGETT

University of Glasgow, UK

A key transformation in archaeology since the 1950s has been the shift from analog to digital. In 1953, Albert Spaulding was one of the first to highlight the potential use of mechanized and electronic methods of processing archaeological data as a means of handling the variety and quantity of data required for statistical analysis (Spaulding 1953). In 1955, Jean-Claude Gardin and Jean Deshayes implemented an optical coincidence punch card system which captured and sorted observations relating to 4,000 Bronze Age metal tools. Two sets of cards were implemented. In the first set, each card related to a single tool, with a matrix of punched and unpunched holes describing the presence or absence of the different features of that tool. In the second set, each card related to a distinctive feature, and the punched holes indicated which tools exhibited that feature (Gardin 1958). Subsequently, in 1959, Gardin and Peter Ihm implemented what is generally accepted to be the first example of a computer application within archaeology, using it to automatically classify the collection of Bronze Age tools (Cowgill 1967). In the United States, James Deetz is credited with the earliest use of computer-based processing in 1960, performing a cluster analysis of design elements in Arikara ceramics (Cowgill 1967).

These early applications of computers in archaeology display two aspects which have colored approaches through to the present day: issues surrounding the description and classification of archaeological objects, and the use of statistical techniques. These were inextricably linked with a concern for the need to capture the richness and complexity of archaeological data within numerical recording systems in order to facilitate computer-based classification and analysis. Typically, this entailed the definition of

a set of descriptive traits along with predefined values for each state, involving the atomization of data and the selection of characteristics that are seen to be relevant. These numerical codes for the differential states of material objects were then considered amenable to quantitative analysis, employing techniques such as automated sorting, classification, and a range of multivariate numerical methodologies.

The creation of a computer representation or digital model of the data necessarily meant that analysis was predicated upon the entities being capable of representation within the digital model—anything that could not be captured digitally could not be incorporated within the model and subsequently within the analysis. Indeed, the construction of the digital data model was seen to entail a highly reductionist approach in which the complexity of the archaeological data was deconstructed into simpler, more basic entities capable of being modeled. This found resonance in the processual or “new” archaeology of the 1960s, in which a more “scientific” approach was closely associated with hypothesis testing, quantification, statistical techniques, and consequently computer applications. As a result, for much of their history, computer applications in archaeology have been closely associated with formal, “scientific,” rather than processual approaches to archaeology, and computerization frequently came to imply quantification (Doran and Hodson 1975).

This highlights a significant tension that has existed within computer applications in archaeology: their association with quantitative rather than qualitative data. The scientific goals and methodologies commonly linked with computers, requiring precision and algorithmic clarity, did not sit comfortably with the more humanistic approaches related with post-processual or interpretive methods developed by archaeologists in the 1970s and 1980s in response to the “new” archaeology. Consequently, the introduction of new computer applications such as geographic information systems (GIS) in the 1980s was perceived in some quarters as being founded upon old, discredited theoretical positions because of

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0108

their apparent reliance on environmental and other nonqualitative data, coupled with their use of quantitative methods.

Key application areas

The growth in computer power and storage capacity alongside its physical reduction from room-scale to desktop and portable equipment associated with the microcomputer revolution of the 1980s is arguably the most transformational development in terms of computer applications in archaeology, continuing through to the present day with developments in handheld and wearable computers. Increased access to and availability of computer hardware and software meant that most archaeologists, in common with specialists in other disciplines, increasingly turned to computers for their day-to-day work. Word processors, spreadsheets, graphics programs, and databases became embedded in archaeological practice. At the same time, the growth in computer usage in archaeology saw a decline in the emphasis on quantitative methods and an increased focus on the production of texts as part of daily professional practice. In the process, most computer applications in archaeology became reliant on off-the-shelf software: as computers became more pervasive, fewer bespoke archaeological programs were required to meet the demands of the subject. Apart from highly specialized areas such as aerial photograph rectification, geophysical survey, and radiocarbon calibration, most archaeological tasks could be undertaken using widely available commercial packages, and, increasingly in recent years, free open source software. A consequence of this was that by the 1990s, archaeological computing could be seen as essentially in a subordinate relationship with other disciplines such as information science, image processing, computer vision, and geographical science, with little novel development taking place within archaeology beyond the application itself. This might be interpreted as evidence of the maturity and ubiquity of computer applications within archaeology or alternatively as a lack of creativity or ambition.

Other than specialized software for highly restricted archaeological tasks, the main computer

application types include database management systems (DBMS), GIS, and visualization systems, with less commonplace being artificial intelligence/expert systems, simulation systems, agent-based modeling, and the continued use of statistical software. These find application across the discipline in areas such as field survey and prospection, excavation recording, post-excavation analysis, local and regional landscape analysis, and cultural resource management. Beyond details of their specific implementation, debates surrounding these applications generally focus on the structuring of data within the various systems and the analysis and visualization of those data in support of the interpretation of the past.

Recording data

From the outset, the preparation of data for computer applications has entailed a process of abstraction: the identification and selection of the entities of interest which are to be represented within the data structures. For example, early archaeological databases, including many regional sites and monuments inventories, were typically implemented in a simple flat-file structure in which data were recorded in a two-dimensional matrix where each entity was represented by a row (record), and their defined attributes by the columns (fields). Archaeologists subsequently embraced the relational database management system which was capable of modeling the relationships between the different archaeological entities as a series of interlinked flat-file tables, and, in the process, reducing the redundancy common in the single flat-file database and simplifying data retrieval by removing the need to search through multiple identical data fields. For instance, a flat-file system would require as many columns as necessary to record the maximum number of artifacts found within a grave, whether or not it actually had any, whereas in a relational system a single grave record in one table would be linked to its accompanying artifacts (if any) in a second table. The abstraction typically required to structure data took complex entities and simplified them in order to capture them, and in the process focused on certain characteristics while discarding others. Since this has implications for the comparability and reusability

of the data by others at a later stage, attempts were made to enforce standards in the definition and recording of data, either by seeking to impose standard software systems or by requiring the use of standardized terminology through the provision of wordlists or more complex thesauri. Inevitably this was resisted in some quarters as a restriction on practice and placing limits on research, but, if anything, the standardization of terminology has assumed a more significant role as data have moved onto the Internet with the potential to be accessed across national and international boundaries, although in this context these standards are commonly applied to data in a post-hoc manner.

Spatial data

GIS were first used in the United States and only saw wider adoption in Europe later in the mid-1990s. The attraction of GIS was the way in which they could incorporate descriptive data with spatial information and provide an accessible integrated system capable of spatially linking multiple data sources: data tables, digital maps and plans, topographic data, geophysical survey data, georeferenced aerial photographs and satellite imagery, hydrology, soils, and a host of other environmental data, for example. Once incorporated, GIS provided a range of tools capable of performing quite complex analyses on the data in a relatively straightforward manner and characteristically generating visual results. Classically, GIS were employed in different ways in the United States and Europe. In the United States, there was a focus on cultural resource management, including predictive modeling to determine the likelihood of encountering sites. In contrast, in Europe the focus was more specifically linked with landscape modeling within a theoretical context to investigate aspects such as movement, visibility, prominence, and proximity. Although these distinctions have broken down with the passing of time and GIS applications have extended into intra-site and excavation recording systems, it remains the case that predictive modeling for cultural resource management applications has not been widely used in Europe, and where it has been applied in the Netherlands, it has since been criticized for its unreliable results (Kamermans 2007).

In terms of data structuring, a recurring issue with GIS is ironically its spatial determinism: unless an entity can be described in terms of a point, line, polygon, or a set of raster values, it cannot be represented within a GIS data model. This enhanced the perception of GIS as a positivist tool, rooted in processual archaeology, and largely incapable of incorporating cultural and social variables. The resurgence of statistical tests of association and spatial analytical techniques within GIS served to reinforce the view that GIS harked back to an earlier theoretical milieu. Although GIS remains a powerful data management and visualization tool regardless, considerable efforts have been expended in attempts to integrate post-processual landscape analyses employing humanistic, cognitive, and cultural variables within the GIS model. This is frequently achieved through the use of proxies—for instance, visibility standing for perception and knowledge of a place—or through the introduction of new tools and procedures for representing movement and vision, for example, although these are often not available within standard GIS packages.

Visualizing data

Visualization, and especially 3D modeling, has seen a significant growth in use in conjunction with the increased availability of fast computers and powerful software. The earliest examples of “virtual archaeology” were produced using mainframe computers and highly specialized software. The incorporation of tools within computer-aided design (CAD) programs made 3D modeling more accessible, although the architectural and engineering origins of the software tended to mean that reconstruction models were frequently of buildings and often classical in nature. Reconstructions tended to be static views, divorced from their surrounding landscape, and lacking any human dimension. The development of 3D animation software and, more recently, the availability of computer gaming environments and their associated assets facilitated the expansion of archaeological reconstructions into much more ambitious interactive virtual environments, with natural features, textures, vegetation, objects, people, and animals. The increased reliance on computer-generated imagery (CGI) in films and

the immersive qualities of computer games has raised expectations of realism and this has created challenges for archaeological reconstruction. In particular, a focus on realistic representation sits uncomfortably with the levels of archaeological interpretation involved in reconstruction—for example, frequently a structure may consist of no more than foundations so that everything reconstructed above ground is based on interpretation and imagination. It has long been accepted that a computer model carries with it connotations of authority, and the degree of realism achieved is often linked to the perceived level of authenticity represented by the model. Communicating uncertainty and the presence of interpretative elements within the same model while retaining the desire for realism is problematic, and approaches generally rely on accompanying documentation or paradata which describes the decision-making process and the construction pipeline used.

Internet archaeology

In concert with wider society, archaeology has embraced the growth of the Internet, and specifically the World Wide Web, since the mid-1990s, and in many respects this has come to underpin computer applications within archaeology. Although initially focused on the creation of web-sites and indices to websites, increasing access to the Web triggered developments in a number of directions. The reliance of the World Wide Web on hypertext markup language (HTML) encouraged exploration of hypertext, which was seen to provide a means of publication suited to a post-processual view of the past by virtue of its subversion of traditional print text paradigms through its perceived erosion of authorship and empowerment of the reader, and the way it enabled interactivity, multivocality, and reflexivity in its texts. However, reality fell far short of vision: the author has remained paramount and the reader subject to the connections created by the author. Contrary to expectation, text is not being decomposed into chunks and massively interlinked; instead, very conventional whole documents, with much of their structure and paper origins clearly apparent, are loosely linked together. As a result, divisions between author and reader, producer and consumer, have

been technologically reinforced. Indeed, with some exceptions (such as the online journal *Internet Archaeology*) the growth of Web-based archaeological publications is largely reliant on delivering text and images in fixed traditional print layouts, such as provided through the Portable Document Format (PDF).

The Internet has been increasingly employed to provide access to archaeological information to a wider audience. Searchable datasets such as national and local heritage records, providing information about site location, period, and events, and typically provided by national and regional heritage agencies, have transformed approaches to desk-based studies in countries such as the United Kingdom, the Netherlands, and Germany. Downloadable datasets, associated with excavations, surveys, and other archaeological interventions, have also become progressively available in the United Kingdom, the United States, the Netherlands, and Germany, with new digital repositories also being established elsewhere. Coupled with this, considerable attention has been paid to the existence of large bodies of archaeological data captured within traditional published journals and in “gray literature” unpublished reports, and means sought to extract relevant information automatically from their PDFs using natural language processing techniques. At a relatively early stage, this draws upon earlier standards of work and aspects of artificial intelligence in order to construct ontologies: structured syntaxes for describing and capturing the concepts and contexts of information and the relationships between them. These provide a means for establishing interoperability between disparate datasets and constitute the “linked data” which underpins the creation of the Semantic Web. Aligning datasets collected by different people at different times and in different places is challenging, and furthermore sits somewhat awkwardly with a situated and contingent view of archaeological information, but the benefits of linking and sharing data are beginning to be demonstrated through large-scale synthetic analyses which would be difficult if not impossible to achieve in their absence.

Making data available in these ways and facilitating their reuse is seen as a key means of ensuring their survival, and this principle underpins archaeological digital archives such as

those provided by the Archaeology Data Service (UK), tDAR (USA), and Open Context (USA). Most professional codes of ethics require archiving of digital data, but there remains a degree of dislocation between the funding of models of these archives and their role as suppliers of data of record: for the most part, funding is insecure, dependent on grant aid or the generation of commercial income. While it is possible to demonstrate the value of these resources in financial terms, this is primarily associated with the benefits of access to online indices and inventories for commercial desk-based analyses, whereas the value of the reuse of archived primary data has proved harder to demonstrate, despite its perceived importance among the archaeological community. With national governments promoting open access to data, heritage agencies are perhaps in a stronger position to support access to data, but again this largely relates to the provision of management inventories rather than primary datasets.

Computing futures

Predicting the future directions of computer applications in archaeology is unlikely to be successful; however, a number of characteristics can be identified. A continued reliance on applications developed in other fields for different purposes may be anticipated, together with the benefits that might accrue—for example, the recent demonstrations of the value of publicly available satellite imagery in the discovery of new sites and tracking the damage inflicted on known sites within conflict areas. The disparate nature of archaeological data, with its variety, complexity, and spatial and temporal dimensions, will continue to be an attraction for the development of linked data and natural language processing. There is also the way in which tools and techniques which may not initially be transformative can subsequently re-emerge in new areas: for instance, artificial intelligence techniques and expert systems never took off in a significant way in the 1980s, but are integral to developments associated with automated data processing and “big data” analysis. Visualization of archaeological data is clearly an area of future growth, and it might be anticipated that it will

expand in new directions—for instance, linking gaming engines and their environments with agent-based modeling—and there is the imminent challenge of virtual reality and augmented reality. In a field that is constantly changing, one thing is certain: that computer applications in archaeology will develop in exciting and unpredictable ways.

Correspondence Analysis

GIANMARCO ALBERTI

University of Malta, Malta

Correspondence analysis (CA) is an exploratory statistical technique that allows us to represent graphically the dependence between rows and columns of contingency tables (also called “cross-tabulations”) in order to discover hidden patterns of association and to facilitate data interpretation. While the foundations of this technique are in the work of K. Pearson and R. A. Fisher, namely in their analysis of contingency tables (see HYPOTHESIS TESTING), the origin of CA can be traced back to the French linguist Jean-Paul Benzécri, who in 1960 developed it in its current form and who can therefore be considered its father. CA has been adopted and further developed by scholars elsewhere in Europe and beyond, so that today different schools can be isolated in continental Europe (e.g., Italy), Asia, Australia, and New Zealand. In archaeology, CA has been slow in gaining popularity by comparison to other multivariate techniques, for instance multidimensional scaling, which was used for seriation purposes as early as the 1970s (Kendall 1971). In the early stages of its development, CA had in fact difficulties in reaching non-French-speaking scientific communities because of the gap between Benzécri’s group in France and Anglo-American statistical schools. Interestingly, early uses of CA in archaeology date back to about the same period when CA’s popularity increased beyond Europe—namely the 1980s. The first applications of the technique to address archaeological problems allow us to detect an early interest in it manifested by central European scholars (Bølviken et al. 1985; Madsen 1989).

CA is particularly well suited to archaeology because archaeological data often lend themselves to contingency tables that cross-tabulate levels of a categorical variable against levels of another such variable. As a case in point, let us consider funerary data (see BURIAL EXCAVATION): a typical

table could put in relation a ‘tomb’ variable with an ‘accompanying object’ variable. As a result, tombs would be listed in the table’s rows (each row representing a burial), while accompanying objects would be listed in the columns (each column representing an object type). Individual cells would contain the frequency with which each object occurs in each burial. Besides being a useful means to summarize data, such a contingency table can be thought of as embedding information about the underlying patterns of association (if any) between rows and columns. To keep the same example, the archaeologist’s interest could lie in understanding the relation between burials and accompanying objects, and especially in assessing whether there is any *correspondence* between a particular burial (or group thereof) and a particular accompanying object (or group thereof). By extension, the aim could also be to assess whether groups of burials characterized by the occurrence of specific objects can be located, or whether groups of objects that occur in specific groups of burials can be isolated.

While the existence and the strength of the association between rows and columns could be tested and gauged via Pearson’s chi-squared test of independence and categorical association coefficients (e.g., Pearson’s phi, Cramer’s V) respectively (see CHI-SQUARE ANALYSIS), the aforementioned goals can be meaningfully addressed with the aid of CA. CA reduces the number of dimensions needed to display a table by decomposing data variability (termed *total inertia* in CA terminology) and by defining the smallest number of dimensions capable of capturing it. The graphical output of CA is a scatter plot where row and column profiles (i.e., sets of relative frequencies into which rows and columns are preliminarily turned) are represented as points on a sequence of low-dimensional spaces. These retain a decreasing amount of the total inertia, whereby the first dimension will capture the highest amount, the second will account for the second largest portion, and so on. On the scatter plot, the distance between data points of the same type (i.e., row-to-row; column-to-column) is related to

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0133

the degree to which the rows have similar profiles. The more the points are close to one another, the more similar their profiles are. The origin of the axes can be conceptualized as the place where there is no difference between rows and columns profiles; or, more formally, it represents the hypothesis of homogeneity of the profiles.

One of the crucial aspects of using CA and interpreting its results is the selection of the number of dimensions to be considered useful for data interpretation. In fact any analyst must face a trade-off between the increase in explained data variability that results from keeping many dimensions and a correspondingly increasing interpretational complexity that derives from choosing more than two dimensions. There are different views on how many dimensions to retain; and they range from informal approaches, whereby only those dimensions to which one can give a meaningful interpretation should be kept, to more formal approaches, such as choosing as many dimensions as are necessary to explain a preestablished level of data variability. Yet other methods exist as well. They comprise the use of the so-called scree plot (first employed in the context of principal component analysis (see *PRINCIPAL COMPONENT ANALYSIS*)) as a visual aid to the selection of dimensions; the retention of dimensions that explain more than the average inertia; the use of chi-squared-based methods such as the so-called Malinvaud's test; and the use of a test allowing to repeatedly perform CA in a randomized fashion, in order to derive a distribution of simulated dimensions against which to compare the dimensions that stem from the observed data. The rationale of this last approach is that nontrivial dimensions should explain a larger percentage of inertia than dimensions derived from random data (for a summary of the methods discussed here, see Alberti 2013, with further references). However, regardless of any compelling dimension-retaining reason, it is often advisable to inspect dimensions other than the first two, since interesting patterns of associations can emerge in higher-dimensionality spaces.

Besides the visual inspection of the CA's graphical output, namely the scatter plot of row and/or column profiles on the plane defined by a pair of selected dimensions, other aspects prove crucial if we wish to gain a rich interpretation of the data structure. The first is assessing which

row or column category is actually contributing to the definition of the selected dimensions; this allows us to understand the 'meaning' of the latter. The second relevant aspect is to assess which row or column categories are more correlated to which dimensions. To accomplish both tasks, the analyst is guided by some CA diagnostics that are routinely reported by any modern computer program, such as the contribution of each row or column category to the inertia explained by the individual dimensions, and the list of the squared cosine. Once the square root of the cosine is calculated, it can be interpreted as a correlation coefficient between each row or column category and the individual dimensions. The squared cosines also allow to quantify how well displayed a row or a column category is on the plane defined by the selected dimensions. For any category, adding up the squared cosine indicates what percentage of inertia is captured by the selected CA plane. The position of points characterized by a low quality of the display must be interpreted with caution.

CA may also provide a basis for formally seeking for clusters among rows or columns (see *CLUSTER ANALYSIS*). A method particularly well suited to the logic of CA uses a progressive aggregation of rows (or columns) in such a way that every successive merging produces the smallest change in the table's inertia. This process can be graphically represented by means of a tree-like diagram and goes on until the table boils down to a single row. Methods also exist to decide how many clusters can be read out from the tree: one such method identifies a cutting threshold at the level at which there is a balance between the within-group and the between-group inertia (Husson, Lê, and Pagès 2011). Another approach proposes to perform a Euclidean distance-based hierarchical clustering using the row or column coordinates on a subset of dimensions in which the data points are well displayed (Ciampi, Marcos, and Limas 2005).

Today CA is widely used in archaeology for different purposes, which range from the study of intra-site activity areas, burial assemblages, and the on-site distribution of faunal remains to the distribution of types of drinking pottery in the context of contact between societies, to stratigraphy and formation processes, or to chronological seriation. The favor encountered by CA in this last kind of analysis is due to its very ability

to highlight and disentangle different trends embedded in the data. CA also has the advantage of not searching for seriation; rather, by dissecting trends in the variability of the data, it reveals whether a seriation structure exists in those data. The presence of such a structure is evidenced by the typical horseshoe (i.e., parabolic) shape of the cloud of row and column points on the CA scatter plot. In such instances, rows and columns of the input contingency tables can be sorted according to the coordinates of the corresponding row and column points on the selected dimensions (usually, but not invariably, the first two). The resulting ordering can be conceived of as having a chronological meaning (in terms of the relative chronology between row and column categories), provided that the input data are sensitive only to time and not to other synchronic factors, such as status, gender, or age, in the case of burial data (Kjeld Jensen and Høilund Nielsen 1997).

The increasingly wider use of CA technique in archaeology as well as in the social science in general is favored by the ready availability of software capable to perform CA. Virtually all commercial statistical programs provide this kind of facility. Even more importantly, CA can be performed by means of a number of free software programs that come either as stand-alone ones (e.g., Hammer, Harper, and Ryan's PAST) or as Microsoft Excel add-ins (T. Madsen's CAPCA). CA is also provided by many packages built to be used within the R statistical programming environment, many of them written by leading scholars in the field of CA computation, as for instance Nenadic and Greenacre's CA, Husson and Pagès's FactoMineR, de Leeuw and Mair's anacor, or Beh and Lombardo's CAvariants. Other packages (e.g., CAinterprTools) aim at facilitating the interpretation of CA's results and allow adding some inferential aspects to the analysis. All these programs can be easily found through a web search. Further, many of them provide the facility to perform other types of multivariate analysis besides CA as well as interesting variants and extensions of CA that have not yet found use in archaeology, for example, nonsymmetric CA, or have been less used than simple CA in this field, for example, multiple CA. Nonsymmetric CA is used

to analyze tables with a dependence structure, that is, tables where rows depend on columns (or vice versa), whereas multiple CA allows the analysis of more than two categorical variables.

Databases in Archaeology

GABRIELE GATTIGLIA
University of Pisa, Italy

The storage of archaeological data in, and their retrieval from, digital databases are by now essential components of archaeological research. Relational database technology was introduced in the 1970s as a way to standardize the data recorded in narrative form (Codd 1970) and provided an important enhancement of the archaeologist's repertory of data analysis tools. Software applications that permit the creation and maintenance of relational databases are superior to traditional, paper-based solutions—superior, that is, in terms of storage, ease of access, space saving, and searching; and their continuous improvement over the past 20 years has led to a widespread use of digital databases in archaeology. Given the growing accessibility of statistical techniques and the ease with which they can be applied, databases have made it possible for archaeologists, who work both as researchers and as professionals, to implement complex quantitative analysis when they examine their datasets.

Databases

A database is usually a collection of data organized for rapid search and retrieval by a computer. It is composed of schemas, tables, forms, queries, reports, and other objects. In other words, it is a prescribed storage area in the computer file system, and it is managed by a dedicated software. Usually the software has a graphical user interface (GUI) that permits easy use toward the creation of a database project. A relational database management system (RDBMS) is a digital database based on a series of tables (or relations) of data linked to one another—that is, designed to

interact among themselves for the efficiency of data organization, avoiding repetition of data entry and data error. Each table is a data structure composed of columns and rows; it has a unique (primary) key that identifies each row, describes relationships between sets of attributes (columns) and records (rows), and represents an entity type, such as a stratigraphic unit (context). The rows are instances of that type of entity (e.g., a single stratigraphic unit) and the columns describe values attributed to those instances (e.g., unit number, components, artifacts). In order to create the tables, it is necessary to know the kinds, quantity, and relationships of the data that one needs to manage (strings, numbers, date, etc.). The relationships among tables are logical models of the relationships between the variables defined for each table. These relationships are fundamental for structuring the tables and their links to one another. They are realized through a column that contains the primary key—that is, a unique index for each row that interlinks all the attributes in the table (e.g., an index that could be used in a table recording stratigraphic units is the number of the unit itself). Each number is unique to each stratigraphic unit, so it may be used as an identifier—say, of the pottery present in a context that is described in another table. In order to link tables, it is necessary to use the key number of the stratigraphic unit as a foreign key that links objects to their context; for example, in a ceramics table, the key number of the stratigraphic unit would link the ceramics in question to their respective context. Generally it is possible to link one single record (row) either to one or to many records. A table also has a user-friendly form, which allows easy entry of data and rapid navigation among the forms. The forms may be grouped into two different user interfaces. The first, where the forms show all the fields of the data-archiving tables, specifically addresses data-entry operators (administrators); the second, where the forms mainly provide query results, specifically addresses users who consult the database. A relational database uses the

Structured Query Language (SQL) for querying and maintaining the database. In the last years of the first decade of the twenty-first century, a generation of postrelational databases called NoSQL databases introduced fast key-value stores and document-oriented databases. NoSQL databases are used with big data approach. Currently a new generation known as NewSQL databases experimented new implementations that are able to retain both the relational/SQL model and the NoSQL model, with its high performance (Moniruzzaman and Hossain 2013).

Databases in archaeology

Planning the architecture of an archaeological relational database should represent a significant effort on the total research design. The database design is aimed at minimizing potential errors in the population and at maximizing data analysis, including the possibility for other researchers to reuse the data. In order to create an efficient database, the organizers of archaeological data should adhere to the rules of archaeological documentation management: it must be as comprehensive as possible and must lead to better analysis, publication, and archiving. Considering archaeological practice, it seems obvious that a single or unique industrial approach is not possible: each project database has to be designed on its own, taking into account the overall research design and expectations for data recording, the project's resources, and the team's technological level. This means that a large part of designing revolves around deciding what types of data to preserve, which attributes are valuable for data collection and analysis, and what relationships are created by choosing these significant attributes (and not others). The choice of the attributes to be recorded (e.g., ceramic type, origin, occurrence) has long-term implications for how a dataset may be reused, whereas the definition of the relationships with other archaeological analytical units—such as sites, archaeological intervention, stratigraphic units, artifacts, and so on—is critical to data analysis and to curation. Open-source software (MySQL, PostgreSQL, SQLite, etc.) versus proprietary software (Microsoft Access, FileMaker Pro, etc.),

cross-platform capability, usability, output, and data integration are all aspects to take care of in the overall data collection and preservation. Ease of access through a wide variety of front-end user interfaces, from GIS to web browsers, increases a database's usefulness to archaeological projects. Unfortunately archaeologists have been slow to take complete advantage of relational architecture, although the latter often mirrors the way archaeological data are structured. The purpose of relational database normalization is to limit each table to a single theme, such as ceramics, which can be related through internal indexes to other tables, such as tables of origin. There is no general rule about the degree and granularity of normalization that should be used. The degree to which data are split into single themes depends upon data organization needs. Generally the core of archaeological databases is their origin (site, archaeological intervention, stratigraphic unit, etc.), given the fact that archaeological data are firmly rooted in locations. Indeed, (geo)location, whether it be intra-site or inter-site, permits archaeologists to meet the basic goals of relational comparison, even if the analytical level at which the location is recorded varies widely from project to project. More granular levels of data collection are represented, for example, by artifacts (pottery, lithics, botanical and/or faunal remains, etc.) inside their stratigraphic unit, and by attributes inside artifact sets or classes.

Thesauri

In order to ensure consistency both within a database and across databases, it is necessary to apply some form of data standards. Central to the application of data standards is the construction of thesauri—lists of values that are necessary for filling in certain fields in guided mode and that control the nomenclature (e.g., site, monument types, pottery types). The importance of thesauri lies in the prevention of inaccurate data and in the searching process itself. In the absence of controlled terminology, searches such as the one for types of pottery are unavoidably compromised. Nonstandardized language can lead to inefficiencies that render the collected data completely unusable.

Thesauri can be divided into:

- closed thesauri, with values that cannot be modified by the searcher; these are vocabularies with a very high level of language processing;
- open thesauri, which do not apply restrictive control of language and allow restrictions to be bypassed through automatic updating when the data are entered. These thesauri are usually adopted for columns for which it is not currently possible to establish a univocal set of values. These vocabularies tend to turn into closed lists gradually, as the reliability of the sample increases. Open thesauri can also be used for data that, given their nature, cannot easily be used in closed lists, for example, fields containing the names of the principal investigator or of the individuals performing the investigation.

Thesauri may be used on their own or organized hierarchically along levels to form an ontology; a good example of the latter is the *Art & Architecture Thesaurus* (<http://www.getty.edu/research/tools/vocabularies/aat>) at the Getty Research Institute.

Chronology

In this context, chronological data management is a key factor in allowing information interoperability. Information is often heterogeneous and dissimilar in terms of chronological definition. Sometimes the data collected also present a certain margin of uncertainty owing to specific contexts or, more generally, to the status of the research. A simple system for managing this information is based on a chronological interval defined by two different number fields called “final chronology” and “initial chronology,” in which the absolute date is included. Centuries can be dated by starting at year 1 and ending at year 100 (the subsequent year). Data can be retrieved thanks to a query—which is conducted on both numerical data in order for an interval to get defined. Number scanning can be accompanied by a chronological thesaurus expressed in text form, which allows for simplified searching:

macroperiods can be divided into subperiods, and so on.

Mobile devices

Mobile devices are the newest and most exciting tools in the archaeologist’s kit. Technologies such as voice data entry, skip logic on touch screens, and wireless networks have opened access to databases and represent a great promise for those who have to enter coded data for large datasets. Thanks to the introduction of tablets (iPad- and Android-based) from 2010 on, archaeologists finally have a device that works all day, is connected to the network even if it does not need it, and has a screen wide enough to allow direct digital entry during fieldwork. In this way the native digital workflow replaces the traditional workflow on paper and opens immediate access to data search and retrieval and to their review. Above all, databases on mobile devices encourage rethinking the best practices for recording and interpreting the past and lead to datafication, which is the act of transforming objects and processes by giving them a quantified format, so they can be tabulated and analyzed. Datafication promises to go beyond digitization and to have an even more profound impact on archaeology, challenging the foundations of our established methods of measurement and providing new opportunities. Indeed, datafication fits a big data approach and permits more sophisticated mathematical analyses dedicated to identifying nonlinear relationships among the data. In other words, to datafy archaeology would mean to produce a flow of data starting from those produced through the archaeological practice, for instance locations, interactions, and relations between finds and sites (Gattiglia 2015).

Because the data management scheme is tailored to the research design, the use of mobile devices to create digital-born data is a decision that each project should make for itself. The PARP:PS project, for instance, experimented with databases running on the iPhone in 2009, and in 2010–12 started using iPads to enter and edit records in the database, draw scaled plans and profiles, keep a free-form notebook, and keep Harris matrices up to date. As a result, the

PARP:PS project has a full native digital archive (Wallrodt 2016, 44).

Descriptive Statistics

SURESH KUMAR SHARMA and
KEWAL KRISHAN
Panjab University, India

TANUJ KANCHAN
All India Institute of Medical Sciences, Jodhpur, India

Introduction

The basic principles of statistics help us to determine what conclusions are reliable and, more generally, provide the navigational guidance for making advances in science and addressing societal issues. Two basic divisions of statistics are inferential statistics and descriptive statistics. While descriptive statistics is concerned with the expression of data, inferential statistics deal with the conclusions drawn from the data/details. Thus, the available information with which we are concerned is called data, and is usually in the form of numbers. The concepts and methods necessary for achieving the objective of summarization are presented in terms of numerical facts, or data, in either tables or graphical form, and with the methodology of analyzing the data. Irrespective of the area of research, descriptive statistics forms an integral part of analysis and presentation of any set of observations. Here we have chosen data simple enough to gain an overview and a better understanding of the topic. Various statistical methods/techniques specifically concerning the various issues in archaeology have been described in the literature (Drennan 2009; Baxter 2010) and cover plenty of archaeological cases.

Some of the necessary words and phrases for an understanding of statistics are listed here:

Population: A population is the universal group from which data are sampled.

Sample: A sample is a part of a population provided it represents the whole population.

Variable: A variable is a feature characteristic of any member of a population differing in quality or quantity from one member to another.

Quantitative variable: A variable differing in quantity is called a quantitative variable, for example, age, height, weight of a person, and so on.

Qualitative variable: A variable differing in quality is called a qualitative variable or attribute, for example, eye color, gender, religion, and so on.

Discrete variable: A discrete variable is the one that can take only certain isolated values, for example, number of members in a family, number of errors in a book, and so on.

Continuous variable: A continuous variable is one which can take all values within certain specified range, for example, age between 20 to 70 years.

Measurement scales: This may be defined as the assignment of numbers to objects or events according to a fixed set of rules. It is important to understand the role of various scales used in statistics. Here is a brief summary of these scales.

- *Nominal scale:* It is categorical in nature and there is no preference for one category over the other. Nominal data has no ordering and it is not metric, for example, gender, religion, and so on.
- *Ordinal scale:* It is also categorical in nature but in this scale order is important. For example, severity of disease (mild, moderate, severe), or socioeconomic class (lower, middle, upper).
- *Interval scale:* On an interval scale, mathematical operations may not be valid. Plus or minus may be valid, but not multiplication and division. It is metric in nature. Moreover, zero has a meaning, for example, temperature, beauty scores, and so on.
- *Ratio scale:* In ratio scale, all mathematical operations (+, −, ×, /) are valid. It is also metric in nature, for example, height or weight. Nominal and ordinal scales are used for categorical data, and interval and

ratio for measurement data (Johnson and Bhattacharyya 2014). Of course, with some expertise, conversions are also possible.

Primary and secondary data: When data is used for the purpose for which it was originally collected, it is known as primary data; when it is used for any other purpose subsequently, it is termed secondary data. For example, if a company buyer obtains quotations for the price, delivery date and performance of a new piece of equipment from a number of suppliers with a view to purchase, then the data as used by the buyer is primary data. Should this data later be used by the Budgetary Control department to estimate price increases of machinery over the past year, then the data is secondary.

Graphical representation of data: A graph is a method of presenting statistical data in visual form. A well-designed graphical presentation can effectively communicate the data's

message in a language readily understood by almost everyone. The graphical methods for describing data are intuitively appealing. They can be used to describe either a sample or a population, and quantitative or qualitative datasets. The different possible methods of graphical representation of data are described below based on a dataset shown in Table 1.

- *Pie chart:* Pie charts are widely used to show the component parts of a total. They are popular because of their simplicity. In constructing a pie chart, the angles of a slice from the center must be in proportion with the percentage of the total (Figure 1a).
- *Simple bar chart:* The horizontal bar chart is also a simple and popular chart. Like the pie chart, the simple vertical bar chart is a one-scale chart. In constructing a bar chart, it is noted that the width of the bar is not important, but the height of the bar must

be proportional to the frequency of that category (Figure 1b).

- *Multiple bar chart*: A multiple bar chart is particularly useful if one desires to make a quick comparison between different sets of data (Figure 1c).
- *Stacked bar diagram*: A component bar chart subdivides the bars in different sections. It is useful when the total of the components is of interest (Figure 1d).
- *Other type of graphs*: Graphical presentations can be made more attractive through the use of careful layout and appropriate symbols. Sometimes information pertaining to different geographical areas can even be presented through the use of a so-called statistical map. A pictograph diagram illustrates statistical data by means of a pictorial symbol. It can add greatly to the interest of what might otherwise be a dull subject. The chosen symbol must have a close association with the subject matter, so that the reader can comprehend the subject under discussion at a glance.

Frequency distributions

Statistical data obtained by means of census, sample surveys or experiments usually consist of raw, unorganized sets of numerical values. Before these data can be used as a basis for inferences about the phenomenon under investigation or as a basis for decision, they must be summarized and the pertinent information must be extracted.

A useful method for summarizing a set of data is the construction of a frequency table, or a frequency distribution; that is, we divide the overall range of values into a number of classes and count the number of observations that fall into each of these classes or intervals. The general rules for constructing a frequency distribution are:

1. There should not be too few or too many classes, generally between 5 to 15.
2. As far as possible, equal class intervals are preferred. But the first and last classes can be open-ended to cater for extreme values.

3. Each class should have a class mark to represent the classes. It is also named as the class midpoint of the i th class. It can be found by taking a simple average of the class boundaries or the class limits of the same class.

These steps may be followed to make a frequency distribution table (Nick 2007): suppose we have a sample of n observations that we want to group. First compute the range (R), that is, the difference between highest (H) and lowest (L) value, say $R = H - L$ (see below). Then the number of classes (k) is computed, using Sturge's formula; $k = 1 + 3.322 \log_{10}(n)$, and then the class interval width (w) is given by $w = R/k$. There are other rules of thumb that are useful in setting up class intervals. Sometimes, a class interval of 5 units or 10 units, and widths that are multiples of 10, tend to make the summarization more comprehensible. However, the rule of thumb is very subjective.

Relative frequency

Often, it is important to know the proportions of observations, rather than the number of observations, falling in a particular class interval. This information can be obtained by dividing the number of values in a particular class interval by the total number of values. For example, if out of the total of 200 values, 40 values fall in the class interval of say 30 to 40, the relative frequency will be $40/200 = 0.20$. Multiplying this by 100, we can say that 20 percent of values fall in this class interval. The proportion of the values falling within a class interval is referred to as the relative frequency of occurrence of values in that interval. This is illustrated in Table 2 and Figure 1e.

Measures of central tendency

In many instances, we need to summarize the data by means of a single number, called a descriptive measure. These measures can be computed for a sample or for a population. If they are computed for a population, then they are known as parameters, while those computed for samples are called statistics. Commonly used measures

Table 2 Frequency distribution of the ages of 169 subjects (male = 91; female = 78).

Age group	Frequency	Relative frequency	Percentage	Cumulative percentage
10–19	4	0.023669	2.4	2.4
20–29	66	0.390533	39.1	41.4
30–39	47	0.278107	27.8	69.2
40–49	36	0.213018	21.3	90.5
50–59	12	0.071006	7.1	97.6
60–69	4	0.023669	2.4	100.0
Total	169	1.0	100.0	

of central tendency are the *mean*, *median* and *mode*. These measures tell how well a typical value represents the large list of values in the dataset. It is useful for summarizing data and defines the center or middle of the data.

Arithmetic mean or average: The mean is obtained by adding all the values in a sample or population and dividing by the total number of observations. It is denoted by $\bar{x}$:

$$\begin{aligned}\text{Mean} = \bar{x} &= \frac{\text{Sum of all observations}}{\text{Total number of observations}} \\ &= \frac{\sum_{i=1}^n x_i}{n}\end{aligned}$$

The mean is a natural and most widely used measure of location, but it is oversensitive to extreme values. In the case of missing or extreme values, the mean is not the appropriate measure of central tendency as it carries the effect of inflation.

Median: After arranging the data either in ascending or descending order of magnitude, the *median* is the middle-most value which divides the finite set of values into two equal parts. If the number of observations (n) is odd, the median lies in the center, and for an even number of observations, it is the average of two middle observations. It is not really affected by extreme values. Sometimes the median is also referred to as the positional average. It can be computed even with missing data, and can be located graphically also.

Mode: The most frequently occurring value among all observations is called the *mode*. For

example, if a set of values is 1, 5, 4, 5, 5, 5, 7, 3, 5, 2, then the mode is 5. The mode also makes sense for qualitative and categorical data, but the mean and median do not. It does not exist if each observation occurs exactly once. If some observations are repeated an equal number of times, some distributions may have more than one mode. A unimodal distribution has one *mode*, a bimodal distribution two modes, and so on.

Measures of dispersion or variability

Dispersion means scatteredness. We study dispersion to have an idea about variability present in a dataset. If all the values are the same, there will be no dispersion. The amount of dispersion may be small, when the observations are close to each other, but it could be large, if they are widely scattered. For example, consider two series with the following observations:

Series I: 1, 5, 9, 13, 17 (sum = 45, $n = 5$, $\bar{x} = 9$)

Series II: 7, 8, 9, 10, 11 (sum = 45, $n = 5$, $\bar{x} = 9$).

Both the series have five observations and have the same mean of 9. Given the information that the mean of the five observations is 9, we can hypothesize whether it represents Series I data or Series II data; but both means are the same. Therefore, mean alone cannot describe the data completely—the missing part is dispersion. The range of Series I varies from 1 to 17 ($R = 16$), and that of Series II from 7 to 11 ($R = 4$). Thus, Series I is more dispersed than Series II or we can

say that Series II is more consistent than Series I. Commonly used measures of dispersion are *range* and *variance* (or *standard deviation*). The square root of variance is the standard deviation.

Range: The difference between the highest and lowest values is called the range, $R = H - L$. The usefulness of range is limited as it depends only on two observations and not on the entire dataset. These values may carry an inflation effect. The main advantage in using the range is the simplicity of its computation.

Variance: This is the most preferred measure of dispersion. It is based on the notion that when the values of a set of observations lie close to their mean, the dispersion will be less, and if they are far away from the mean, dispersion will be greater. In computing the variance, we subtract the mean from each observation, square the resulting differences, and add up the squared differences. This sum is then divided by the sample size minus 1, to obtain the sample variance, and by the sample size (n), for

population variance.

$$\text{Variance} = \sigma^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2$$

$$\text{Standard deviation} = \sigma = \sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2}$$

The variance represents squared units and it is not an appropriate measure of dispersion when we wish to express this concept in terms of the original units, and therefore standard deviation is preferred as a measure of dispersion in original units.

Coefficient of variation: When we want to compare the two or more given series in terms of standard deviation or variance, it may lead to fallacious results as they are measured in different units. In such situations, we use *coefficient of variation (CV)*, which express the standard deviation as a percentage of mean. The formula is given by:

$$CV = \frac{\sigma}{\bar{x}} \times 100$$

Figure 2 Distributions for negatively skewed, symmetrical, and positively skewed data.

Figure 3 Kurtosis.

Since the mean and standard deviation are measured in the same units, they cancel out in computing the *coefficient of variation*. For sample observations, we replace σ by s (the sample standard deviation).

Partitioning values (percentiles and quartiles): The mean and median are special cases of a family of parameters known as location parameters, so-called because they can be used to designate certain positions on the horizontal axis when the distribution of a variable is graphed. For example, a distribution with a median of 150 is located to the right of a distribution with a median of 100 when the two distributions are graphed. Other location parameters include percentiles and quartiles. We may define a percentile as follows: given a set of n observations, the p th percentile P is the value of a variable such that the proportion p of observations is less than or equal to P and the proportion $(1 - p)$ of the observations is greater than P . Subscripts on P serve to distinguish one percentile from another. The 10th percentile, for example, is designated by P_{10} and the 70th by P_{70} . The 50th percentile, P_{50} , is the median. The 25th percentile is often referred to as the first quartile and it is denoted Q_1 . The 50th percentile (the median) is referred to as the second

quartile Q_2 . Similarly, the 75th percentile is referred to as the third quartile Q_3 .

Interquartile range: A disadvantage of the range is the fact that it is computed from only two values, the largest and the smallest. A similar measure that reflects the variability among the middle 50 percent of the observations in a dataset is the interquartile range. The interquartile range (IQR) is the difference between the third and first quartiles: that is, $IQR = Q_3 - Q_1$.

Box and whisker plot: This is a very useful communicating device containing information about data. A box is drawn between Q_1 and Q_3 , the lower end of the box placed at Q_1 and the upper end at Q_3 . The box is then divided into two parts by a horizontal line that aligns with the *median*. It is generally drawn for comparison purposes. The box and whisker plot drawn for the ages of 169 participants is shown in Figure 1f. The importance of the box plot lies in the fact that it can identify outliers. An outlier is an observation that lies away from the main body of the data. The box plot identifies two types of outliers: probable (marked as 'o') and extreme outliers (marked as '*'). For example, there is one probable outlier among males in Figure 1f.

Moments (definition): The r th-order central moment of a variable x is defined as:

$$m_r = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^r, \quad r = 0, 1, 2, \dots$$

Note that $m_0 = 1$, $m_1 = 0$ always, and m_2 corresponds to the second-order moment, which is equal to σ^2 , the variance, as defined earlier. m_3 and m_4 are called the 3rd- and 4th-order moments. These moments are helpful to determine skewness and kurtosis.

Skewness: This means “lack of symmetry”. We study skewness to have an idea about the shape of the curve that we can draw with the help of given data. A distribution is skewed if:

- 1 Mean $\neq$ median $\neq$ mode.
- 2 Quartiles Q_1 and Q_3 are not equidistant from the median (see box plot).
- 3 The curve drawn with the help of given data is not symmetrical, but stretched more to one side than to the other.

The figures given below show distributions for negatively skewed, symmetrical and positively skewed data (Figure 2). Skewness can be measured either using absolute measures or relative measures, but the best measure of skewness is based upon moment given below:

$$\text{Skewness} = \beta_1 = \frac{m_3}{m_2^{3/2}}$$

where m_3 and m_2 are third- and second-order moments, computed from the given data. If $\beta_1 > 0$, the distribution is positively skewed; if $\beta_1 = 0$, the distribution is symmetrical; and if $\beta_1 < 0$, the distribution is negatively skewed.

Kurtosis: This is a measure of peakedness of the curve. Even if we have measures of central tendency, dispersion and skewness, still we cannot form a complete idea about the distribution, as shown in Figure 3. Kurtosis is measured by coefficient β_2 or its derivation γ_2 given by:

$$\text{Kurtosis} = \beta_2 = \frac{m_4}{m_2^2}, \quad \text{or} \quad \gamma_2 = \beta_2 - 3$$

For a normal curve (also called a *mesokurtic curve*), $\beta_2 = 3$ or $\gamma_2 = 0$. A curve which is flatter than the normal is called *platykurtic*, and for this curve, $\beta_2 < 3$ or $\gamma_2 < 0$. Similarly, the curve that has a higher peak than the normal is called *leptokurtic*, and for this curve $\beta_2 > 3$ or $\gamma_2 > 0$.

Digital Heritage

SUSAN HAZAN

The Israel Museum, Israel

We are all products of our own society by the very result of being born into a family and a community. We may not even be aware that the heritage that surrounds us is ours—it is simply there—it is intrinsic to our sense of self, and is the anchor that sustains and centers us (Bourdieu 1999). Stepping out of our own comfort zone can be exciting, but acknowledging and respecting another's heritage is how society maintains its integrity and social cohesion. We are witness to vast quantities of new objects entering this cultural ecosystem on a daily, if not hourly rate. Artworks and unique, handmade objects are continually being created and circulated, entering the marketplace to be purchased, collected, and exhibited in the public domain for our appreciation and pleasure. At the same time archaeological excavations are revealing vast quantities of new objects, and with them come their compelling narratives from distant times (see TIME AND TEMPORALITY).

According to The New Renaissance, *Report of the Comité des Sages*,

... new information technologies have created unbelievable opportunities to make this common heritage more accessible for all. Culture is following the digital path and 'memory institutions' are adapting the way in which they communicate with their public (2011, 8).

We are currently witnessing an exponential growth of heritage resources traveling through the digital ecosphere and reaching us from beyond the traditional restraints of space or time. This explosion of digital cultural assets may be seen as a perplexing cacophony, but once organized into intuitive datasets, and made machine readable, they may serve to enrich our

lives when conveyed to us wherever we may be—even directly into the palm of our hand. The challenge we are now facing is how to be able to describe, collect, collate, and disseminate all these archaeological treasures as digital objects, and to be able to wrap them and deliver them together with their descriptions and histories. From the moment that objects are discovered in an excavation and identified, collated, and documented, they are put into systematic order to facilitate analysis, research, and inevitable enchantment by those lucky enough to encounter them. Digital, cultural heritage, once encapsulated with the details of their provenance (metadata), can then be released back into the cultural ecosystem as meaningful narratives and serve to inculcate our sense of self and community.

The veritable explosion of digital possibilities now available to all is almost bewildering, while at the same time the thirst for heritage for individuals and society is almost unquenchable. The insatiable snapping of "selfies" attests to this almost obsessive need to document ourselves, but people also desire to see themselves as fully wrapped in a cultural mantle. There is no better way to understand who we are than by connecting to our histories, and to the structured narratives that move through electronic networks. We can then begin to appreciate our heritage once it is rendered as a comprehensive mapping of society over time and space. There is no single heritage or archaeological sector that remains unaffected by the incredible leaps and bounds of digital possibility. Archaeologists have been documenting objects in the field as they digitize their discoveries in situ. From dig to smartphone, the route is almost a straight line. At the same time, the creative industries are fully engaged in creating platforms and tools to enable the celebration of cultural assets, once the exclusive prerogative of the galleries, libraries, archives, and museums community (GLAM), but now reaching us over websites, portals, mobile apps, and social networks. The results are more than remarkable.

Still underdeveloped at this time is the systematic linking of heritage within open systems, though digital enterprise. Linked open data (LOD) as a method of linking machine readable assets is still in its infancy, as are solutions developing specifications and standards to support the use of knowledge organization systems (KOS), such as thesauri, classification schemes, and taxonomies within the framework of the Semantic Web. Methodologies such as the Simple Knowledge Organization System (SKOS) are still evolving. This kind of open and systematic linking of assets will serve to open up, and provide direct access to, heritage for everyone—all available in your own language, to be treasured, and savored at your own pace, wherever you are.

The following sections will discuss the circulation of objects in the digital ecosphere of cultural heritage, from the top-down management of cultural heritage to the GLAM community's custodianship of heritage collections and their digital management and telemanagement of archaeology—the evolving visualization platforms that enable the sharing of heritage in the public sphere such as augmented (see AUGMENTED REALITY) and virtual reality (see VIRTUAL REALITY MODELING).

Top-down management of cultural heritage

The term “culture” can be interpreted in different ways and may be mobilized for different agendas. Drawing on the United Nations Educational, Scientific and Cultural Organization (UNESCO) treaty and the Convention Concerning the Protection of the World Cultural and Natural Heritage (see HERITAGE AND POLICY), The World Heritage Convention, adopted by UNESCO in 1972, describes heritage as “... our legacy from the past, what we live with today, and what we pass on to future generations. Our cultural and natural heritage are both irreplaceable sources of life and inspiration.”

According to UNESCO, cultural heritage has the power to transform societies and enrich our lives in countless ways, reminds us how heritage constitutes the core of our identity,

and lays the foundations for vibrant, innovative, and prosperous knowledge societies. Inspired by this directive, the legacy of unique, and often irreplaceable, tangible objects is handed down from past generations to GLAMs, who then assume the stewardship of the cultural and natural heritage on behalf of society. With this responsibility comes the obligation to collect, conserve, and make collections accessible to the public as exhibitions in the present, and to preserve them for the benefit of future generations. In addition to the physical objects circulating in the cultural realm, UNESCO recognizes tangible heritage as encompassing buildings and historic places, monuments, artifacts, and so forth, that are considered worthy of preservation for the future. These include objects significant to the archaeology, architecture, science, or technology of a specific society. In 1994, the World Heritage Committee launched the Global Strategy for a Representative, Balanced, and Credible World Heritage List (see WORLD HERITAGE SITES DESIGNATION) to recognize sites that are of outstanding universal value and meet at least one of ten criteria, selected on the basis of six cultural and four natural criteria.

Heritage is not only about physical objects, however. It also embraces traditions and creativity inherited from our ancestors in an awareness, aware that they are to be valued and passed on to our descendants (see COMMUNITY HERITAGE). Intangible heritage includes, according to UNESCO principles, oral traditions, performing arts, social practices, rituals, festive events, knowledge and practices concerning nature and the universe, and the knowledge and skills to produce traditional crafts. Thus, the tangible and intangible come together to weave the warp and weft of our communities, and the very fabric of our society.

Galleries, libraries, archives and museums (GLAM) community's custodianship of collections

Managing heritage as objects means accessioning them into institutional collections, but as soon as they cross the threshold of past and present they automatically become fossilized

in the historical past. This represents a heterotopian space; a cultural entity that is locked outside of the temporal pace of daily life; a place where the temporal discontinuities cause time to stand still and objects to become fixed in a frozen moment. Foucault (1994, 182) draws attention to the mausoleum-like nature of the modern museum when he describes museums as connected to these temporal discontinuities; as heterochronias—“in which time never ceases to pile up and perch on its own summit.” While heterotopias may be seen as non-places (Augé 1995), as physical spaces that have been geographically misplaced, Foucault recognizes how museums (and libraries) act as heterochronias, and a phenomenon to which he refers as symptomatic of modernity. This resolutely immutable collection of all things that Foucault describes brings to mind a dull and dusty place, where the objects have been so abstracted from daily life that they represent the dead rather than the living. For a museum to be meaningful to living people, the mere preservation and conservation of the historical past is not enough. The act of collecting must be combined with processes of production and interpretation that reunite objects with their provenance and wrap them up into their cultural essentiality. Social anthropologist Alfred Gell (1992) celebrates the wondrous nature of these kinds of objects when he describes the way that anthropological artifacts come into being. He suggests that these objects are the result of a process that emphasizes the technical miracle that must be distinguished from a merely mysterious process. “It is miraculous,” according to Gell, “because it is achieved both by human agency but at the same time by an agency which transcends the normal sense of self-possession of the spectator.” This technical miracle evokes a profound sense of awe in the beholder, a potent intuitive response that Gell identifies as the “halo-effect.” This is the visceral response to wondrous objects that stop you in your tracks when you encounter them on display under an almost hypnotic spotlight and an elevated pedestal.

How to encapsulate these halo-effects, and at the same time release these precious objects from their dusty corners and propel them into the ether of the Internet, is one of the challenges facing the GLAM community today. Objects lose

their spotlight magic once the electricity is turned off in the gallery, and they are diminished further as they are photographed as mere shadows of themselves as digital images, so tiny that they fit snugly into your smartphone—doing little to replenish their lost luster. This is further abstracted by viewing them in a browser, or app, reducing their essence even more as they leave the relative safety of their institutional provenance. The disparity between the real and the virtual is often cause for concern—where these digital specters, depleted of their cultural essence, jostle with other digital entities online to become viral over social networks. As early as 1995 Sherry Turkle addressed the ways that people interact with computers, and the consequences of that interaction. We are still somewhat wary of peering at our screens, while at the same time passionately seeking the information, images, and narratives that we all crave so much. One of the ways to resolve this dichotomy is not to think about the real and virtual as diametric opposites. Pierre Lévy takes exception to the ideas of real and virtual as dialectical counterparts, and argues that

“virtualization, or the transition to a problematic, in no way implies a disappearance in illusion or dematerialization. Rather it should be understood as a form of ‘desubstantiation’ [...] the body as flame, the text as flux” (Lévy 1998, 169).

With an emphasis on heritage and archaeological assets, the following section will consider the management of heritage collections, not as truncated objects that have lost their stories, nor as stories that have become dislocated from their source, but as vibrant entities whose whole consists of a number of parts: the physical and digital, the tangible and intangible, the image and the narrative.

Managing the digital collection and telearchaeology

There are many novel terms describing the management of archaeological assets: teleimmersive archaeology, cyberarchaeology, telearchaeology,

digital archaeology, all aiming to release archaeological, historical, artifacts dug from the depths of the excavation to be transformed into archival data; to move seamlessly from the field and be shared by scholars on the Web (see *COMPUTER APPLICATIONS IN ARCHAEOLOGY*). There is now an understanding that the popular program FileMaker, the database system (see *DATABASES IN ARCHAEOLOGY*) that is used by many archaeological teams, is but part of the chain of events needed to create paperless archaeology. The key to success is the understanding that all data are born digital at the locus level, where spatial data, 3D models, photogrammetry, excavation records, and images are all collated in the field, and processed on the fly to generate and document a total paperless excavation. An example of this kind of holistic approach can be seen in the Jezreel Valley Regional Project (JVRP). The JVRP is a long-term, multidisciplinary survey and excavation project investigating the history of human activity in the Jezreel Valley in Israel from the Paleolithic through the Ottoman period. The interface design for JVRP was built for a field methodology and registration workflow that included synchronization with total station measurements and self-generated context summaries. Major database development was a necessity during the field season and was provided by CoDA, founded by a group of faculties and researchers from University College Berkeley, USA and established as a California 501(c)3 nonprofit organization in April 2011. What was most spectacular about this approach was how their data flowed using CIDOC Conceptual Reference Model (CRM) to be published as linked open data to the Semantic Web in real time.

The Priniatikos Pyrgos archaeological project has taken a similar approach where they also concurred that the FileMaker system was too isolated from other archaeological datasets. In his paper, Lynam (2015) describes the process of using ontologies to structure digital archaeological datasets for publication on the Semantic Web. Open data, linked data, and the Semantic Web fully mapped to CIDOC CRM. The CRM was originally conceived to manage museum and archive material, but its core set of classes and predicates are now extended to include structured archaeological data. The

key to the flexibility of the model states that material objects are transformed when they move from one context to the next, where archaeological context can then adopt different meanings as they are affected by one event after another. The introduction of these kinds of schematic relationships, integrating artifact, time, place, and location into a seamless whole, together with the automation of machine-driven processing, means that cultural heritage can be liberated in innovative ways, made visible across different domains, even across related professional sectors, and interrogated alongside similar datasets. Once the cultural heritage community has agreed on common ontologies, controlled vocabularies, or thesauri, this methodology, enabled by the Semantic Web, facilitates highly complex querying built upon the principles of open data and linked data practice.

Visualization platforms, augmented and virtual reality

With a responsibility to preserve heritage resources from the past and a commitment to present it to the public in the present, as well as the obligation to conserve and relay it to future generations, together with the ability to document, describe, and disseminate heritage resources over the Semantic Web, we are now poised to create new kinds of experiences that not only interpret, but celebrate heritage resources and make them accessible to all (see *DIGITAL MEDIA IN ARCHAEOLOGY*). Three-dimensional worlds can be created to recall lost histories; oral traditions can be recorded, reenacted, and shared from one community to the next and from one generation to the next, as tangible and intangible heritage can be augmented and reinserted into previously hidden, even lost narratives. With all this digital potential, there is nothing to stop the imagination, and human creativity, calling up compelling scenarios based on heritage resources from other times and distant places, to be transmitted over the holodeck of virtual reality. This section will discuss two examples from China and London, United Kingdom.

Created by Professors Sarah Kenderdine and Jeffrey Shaw at the City University of Hong Kong in 2012, *Pure Land: Inside the Mogao Grottoes at Dunhuang* is a 1:1 scale virtual facsimile that reframes and reconstitutes the extraordinary wealth of the seventh- and tenth-century paintings found in the caves at Dunhuang, created by, and in partnership with, the custodians of the Mogao Grottoes, the Dunhuang Academy. Regrettably, the Grottoes are threatened by rising levels of humidity and carbon dioxide due to their popularity as a tourist destination, and the virtual reconstruction offers a means of granting access to heritage resources without endangering the heritage itself. Incorporating laser scans of the cave architecture and high-resolution photographs, the augmented-reality installation generates a virtual reconstruction of a Tang dynasty cave, one of the world's great treasures of Buddhist art. The embodied encounter allows visitors to experience the architectural elements and the murals as if they were entering the cave themselves, and, due to the pictorial recoloring, digital enlargement, and a rich sound design, visitors can explore the cave as a multilayered, multimedia interactive drama. These kinds of heritage-driven narratives provide ground-breaking technological and operational opportunities for the future of digital preservation; a paradigm shift for the dissemination of heritage interpretation; and exciting new ways to experience embodied heritage resources.

Elsewhere, far away from the depth of the caves, visitors can explore heritage resources through a shift in time simply by walking down the street. Incorporating images by photographers Henry Grant, Wolfgang Suschitsky, Roger Mayne, and George Davison Reid from the Museum of London's extensive collections, and developed to mark the opening of the New Galleries of Modern London exhibition in 2011, Streetmuseum presents a hybrid perspective of historical and contemporary London. By pointing your smartphone at one of London's famous landmarks and selecting a destination from the London map or using your GPS to locate an image nearby, the app superimposes historic images of London over the present-day view. The Streetmuseum app now has over 100 locations and images, ranging from 1868 to 2003, offering historical

juxtapositions of London locations enhanced with historical information about each one. This digital window compresses time and space in a single swipe of the screen, and offers unique glimpses into many years of the city's tempestuous history.

These kinds of culturally enriched digital platforms not only sustain rich narratives but enable them to fold into heritage, or open up new pathways for self-directed learning and creative ways of thinking about self, past and present.

Digital Media in Archaeology

WILLEKE WENDRICH

University of California, Los Angeles, USA

Archaeology is a discipline that from its very beginnings has depended on multiple media to convey the results of its research. The recording of archaeological excavations and finds has always been a visual process. Based on handwritten notes and sketches in diaries, archaeological recording was supplemented with the work of artists, architects, and surveyors, who created drawings, plans, and maps. Early photography was employed to create what was perceived as more “truthful” imagery of archaeological remains, and was part of empirical research that often combined archaeology with anthropologic and geographic exploration (Hannavy 2008).

The number of media employed in archaeology has risen exponentially with the increase in multidisciplinary and technical innovation. Photography, most often black-and-white photographs for printing and color slides to be used in lectures, became a mainstay for field and finds recording. Basic rules for photography were developed, so that each site photo had a scale and north arrow, while each object was photographed with a (color) scale from multiple directions (Bohrer 2011). Apart from architectural plans, the use of theodolites, and later total stations, enabled exact recording of the location of excavation trenches, walls, soil units, and (noteworthy) individual objects in situ (see TOTAL STATION). Methods were created for object drawing, standardizing the location of the light source (upper left corner) and shading (Griffiths, Jenner, and Wilson 2007), as well as the different views and cross-sections that needed to be drawn for each type of object. Ceramicists developed a drawing standard that included a reconstruction of the rim diameter and shape of the pot, based on diagnostic (rim, handle, and base) sherds. With an increased interest in methodology, the

purpose of drawings versus photographs was summarized in an ideal approach combining the two: photography was faster, but less engaged, while drawings enabled one to emphasize certain aspects and look at objects in different types of light, so details that could not be made visible in photographs could be filled out. Drawing also enabled reconstructions of objects, buildings, or entire ancient lifeways. Film and video were used sparingly in archaeology, mostly to record (or reconstruct) moments of spectacular discoveries, which was useful for fund-raising and informing the general public, but also to record the process of archaeology. Ethnoarchaeological research (see ETHNOARCHAEOLOGY) employed photography, film, and video widely to record aspects of present-day society that provide information on archaeological research questions often in support of analogical reasoning, but more successfully in attempts to counteract cultural limitations in understanding the past and undermining preconceived notions of the researcher.

Multidisciplinary teams, with specialists studying different materials or artifact groups and producing additional notes, photographs, and drawings, created a rich body of knowledge, which appeared difficult to cross-reference. Usually only the editor of the final publication would gain insight into the different lines of evidence. Multimedia were, therefore, closely linked to one of the last phases of the archaeological work: the publication. Text with a selection of drawings, photographs, and maps was part of every traditional archaeological publication, often divided into chapters per artifact group and ideally integrated in a final concluding chapter. The final phase of the archaeological research process, archiving, again split the various media up into slide libraries, map drawers, negative binders, and notebooks, due to the varying preservation requirements for each type of medium.

With the digital turn in archaeology, the multimedia landscape has changed dramatically. It is not just that digital photography is affordable and that the number of photographs typically taken by archaeologists has risen exponentially.

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

It is not just that the traditional methods are becoming less relevant, with hand-drawing being replaced with photography or photogrammetry and specific lighting techniques, such as infrared photography and reflectance transformation imaging (RTI), that allow for a differentiation in lighting to bring out details that are not even visible with the naked eye. It is not just that three-dimensional (3D) modeling of ongoing excavations is adopted widely by using structure from motion (see *STRUCTURE FROM MOTION*), in which software is used to create the geometry of a landscape or object from photography. While these developments have altered the methods archaeologists employ to capture data, the most important change is that it has become feasible to integrate different digital media, and that photographs, drawings, maps, visualizations, and video are increasingly considered as information on equal footing with quantitative and qualitative data. Almost every excavation uses databases and spreadsheets, but, while possible, joining field information seamlessly with photographs, maps, and the study results of specialists frequently remains elusive. This is in large part because a digital excavation requires a specific and coordinated workflow to ensure that all types of information can be connected. One feature that all archaeological information has in common, for instance, is location. Geographic information systems (GIS) can be used as a basis, which allows for all aspects of an archaeological project to be linked, but photographs similarly can provide an entrance to the entire data landscape. Digital media thus form a network of interconnected data in many different shapes, but with one basic output: the screen.

Twenty-first-century archaeologists collect data in different forms for various purposes. Surveying results in a digitally born map (see *DIGITAL CARTOGRAPHY*) using total station or differential global positioning system (DGPS) points downloaded directly into the GIS. Apart from the traditional digital media, digitized texts, spreadsheets, databases (see *DATABASES IN ARCHAEOLOGY*), photographs, drawings, videos, and GIS, archaeological research also has to take into account increasingly large file types linked to documentation and analytical instruments, such as ground-penetrating radar (see *GROUND-PENETRATING RADAR*),

magnetometers (see *MAGNETOMETRY*), light detection and ranging (LiDAR) (see *LIDAR DATA VISUALIZATION AND PROCESSING*), 3D scanning (see *LASER SCANNING*), and other nondestructive approaches, as well as dating methods (see *DATING IN ARCHAEOLOGY*), scanning electron microscopy (see *SCANNING ELECTRON MICROSCOPY*), Raman spectroscopy (see *RAMAN SPECTROSCOPY*), X-ray diffraction, (portable) X-ray fluorescence spectroscopy (see *PORTABLE X-RAY FLUORESCENCE SPECTROMETRY (PXRF)*), and gas chromatography combined with mass spectrometry (see *GAS CHROMATOGRAPHY-MASS SPECTROMETRY (GC-MS)*), to name but a few.

As with traditional publication, most of this information comes together when the results of all participants are gathered, usually close to the publication date. Experiments with hybrid digital media publications are ongoing. Instead of selecting a few photographs, a printed or digital publication can link to a large number of high-resolution color photographs with the information of what they depict, and (perhaps most importantly) what the relevance is of their subject. Instead of printing a page-size map which can hold limited information, including expensive fold-outs or unattached easy-to-lose large-format maps, the text can link to an interactive searchable map online. Zoom level can be connected to a specific data density or data type and automatically display the information that is relevant to a particular scale. Instead of filling many pages with printed tables, an increasing number of publications link to online spreadsheets or databases. Where in the past reuse of information required the retyping of tables, with all the human reading and typing errors that such an exercise inevitably introduces, the future will hopefully bring a sturdy linked data landscape. Linked open data require information and knowledge to be exposed, shared, and connected on the World Wide Web using persistent unique identifiers (uniform resource identifiers (URIs)) and a conceptual framework to describe these resources (resource description framework (RDF)), organized through ontologies as part of the Semantic Web (see *SEMANTIC WEB AND ONTOLOGIES*) (Richards 2006).

The power and promise of digital media derives from the speed and efficiency at which connections can now be made among various

types of data, thereby creating a more direct path between field research, laboratory analyses, and dissemination. A further advantage, which is rapidly becoming the new normal, is that the original data output as well as the interpretation can be linked to a site report, the overall broader conclusions, as well as any other information relevant to the area or objects under investigation. Through the wide availability of digital media, publication has the potential to provide overarching conclusions that can be traced back all the way to the original observations, measurements, and interpretations, facilitating not only reuse of the data but also reproducibility of the results. This is extremely important for a discipline that considers itself a science, a social science, and a humanistic endeavor, often all at once.

There are several additional advantages to digital media publication. Moving beyond hypertext (the in-text clickable links), a connection of different media types forms a knowledge base that can be used in a nonlinear way. It frees the users from following the narrative in a text as determined by the authors. Images can function as an access point to the text and, similarly, map-based information and databases can be queried separately, providing insights and knowledge that go beyond what is presented by the excavators. This heuristic potential becomes even stronger if data from multiple projects are available and can be linked (Geser 2016).

The use of digital media in archaeology still presents considerable problems, which can only be solved if archaeologists are aware of and adhere to good practices. Much of the information is gathered with proprietary soft- or hardware. This means that such formats can only be shared if all users purchase the same equipment or use the same programs and platforms. Only if the package or instrument enables export in an open data format is reuse of the data and more importantly reproducibility of the results possible. This also requires being explicit about the method used, including the workflows, ways of measuring, tools, and algorithms. Much has been written about metadata, which is the information that describes in detail how we should understand the data. This includes, for instance, the name of the person who took the photograph, did the measurements, and wrote the interpretation, but also to what these data pertain exactly. The long-term

preservation of digital research data is as yet uncertain. For archaeological data this is particularly urgent, because the mere activity of excavation destroys the layers that contain the information on which our interpretations and explanations are based. The importance of the preservation of digital archaeological research in its many forms is gaining recognition. There are two major repositories for archaeological data—the Archaeological Data Service (ADS) in the United Kingdom, and the Digital Archaeological Record (tDAR) in the United States—that offer not just data back-up, but also migration to new versions of software and hardware systems. There are several publication initiatives that team up with these and other repositories (such as university-based digital libraries). Examples of these are the Digital Information Gateway (DIG) (<http://dig.ucla.edu/project>), Internet Archaeology (<http://intarch.ac.uk/>), the Journal of Open Archaeology Data (JOAD) (<https://openarchaeologydata.metajnl.com/>), Open Context (<https://opencontext.org/>), and Advances in Archaeological Practice (<https://www.cambridge.org/core/journals/advances-in-archaeological-practice>).

Apart from the uncertainties around preservation, there is a continued need for a critical approach to the perception of different media. Many of these concerns are no different than those pertaining to the traditional information, and specifically the visual aspects of traditional multimedia. Photographs and video have mistakenly been considered as objective records of a given situation, while they convey the literal and mental viewpoint of the photographer (Bohrer 2011). It is not just the camera position that influences how we see through the lens of the film or video camera, but also whether we are shown the world in overview or close-up. What is excluded from the image is sometimes as important as what is included. During editing, the entire narrative can be changed from what the original situation was. Interventions such as changing the order, adding a speaker's words to a different bodily attitude or facial expression, or adding voice-over or music all result in a particular understanding and interpretation of the visual media.

Visualizations are persuasive and strongly influence the understanding and memory of what is depicted (Molyneaux 1997). Much of this understanding is subconscious, and even

if the author explicitly writes a disclaimer next to an interpretative illustration, the text will not affect the memory as strongly as the image. This is especially true for interpretations and reconstructions, but also the visual representation of archaeological data is far from objective. Charts or maps can give accidentally misleading impressions or provide the opportunity for outright manipulation (Monmonier 1991; Tufte 1990; Wendrich 2010).

These caveats are no different for digitally born representations, although the availability of the original data provides users with the capability to check data visualizations. That does not, however, guarantee the quality of the data themselves. Tools that routinely spit out digital results, such as automated survey or geophysical instruments, are a black box that might generate nonsensical results if the user is not aware of the process and lacks the ability to estimate what outcome is expected. A lack of awareness of how these black boxes are generating their output sometimes results in adjusting parameters based on biases, instead of understanding the mathematical or algorithmic processes.

The future of digital media is not necessarily completely born-digital. Creating illustrations and plans by hand still has its use, especially in the context of training and archaeological field schools. Drawing by hand forces the archaeologist to pay close attention. This not only repeats observations done during excavation, but often allows new or corrected results. Drawing requires a scrutiny and precision that is not equaled by photography. Those hand-made drawings can be digitized and incorporated in a rich data landscape. With the fast-growing capabilities of digital visualizations the next step will be an “immersive archaeology” where excavation data, interpretations, and reconstructions can be explored in a virtual reality environment (see VIRTUAL REALITY MODELING). Such a 3D representation of the world based on archaeology has an even stronger level of intrusiveness in the brain than drawings and requires a firm grounding in the data that we have, as well as an indication of the information that we do not possess. The heuristic power of digital media needs to be clothed in a careful presentation of data. In this respect, the terms *metadata* (the information that says something about another data carrier, such as a photograph

or a table) and *paradata* (the information that underlies a reconstruction, such as antique paintings or descriptions of ancient architecture) are not very useful categories, because data are agnostic of the use they are put to. Depending on our research question, all types of data can provide relevant information and all types of data are a form of digital media.

Digital media have the potential for broad distribution, which opens up access to archaeology outside the European/North American academic world and communities of nonprofessional audiences. Digital media can thus support efforts to bring archaeology into the community (see HERITAGE AND COMMUNITY ARCHAEOLOGY) and can help decolonize archaeological practices: The availability of all information will provide the avenue to check reports with a critical research approach, so that biased interpretations can be pointed out. The promise of digital media can, however, only be realized if the archiving problem can be solved and if archaeologists no longer consider data sharing as a gesture of generosity, but as an obligation of research groups and as a fundamental outcome of archaeological work.

Distance and Data Transformation

HANS-JOACHIM MUCHA

Weierstrass Institute for Applied Analysis and Stochastics, Germany

HANS-GEORG BARTEL

Humboldt University of Berlin, Germany

In archaeological sciences, data of various kinds are collected and/or measured in order to be evaluated properly by multivariate statistical methods. Usually, these data are organized as a matrix $\mathbf{X}$ with I rows that correspond to archaeological objects, and J columns (variables) that correspond to attributes describing the archaeological objects. These may be glass, metal and ceramic artifacts, Mousterian bifaces, archaeological deposits, inscriptions, images, skulls, pottery, ancient Roman bricks or tiles (Mucha, Bartel, and Dolata 2008). Attributes of such artifacts may consist of quantitative measurements such as chemical composition, and/or categorical data such as color. A special case is binary data such as absence/presence or yes/no.

The concept of distance (dissimilarity) is about quantification of how far apart any two archaeological objects are. Various distance measures can be applied to quantitative and/or categorical data. By using these pairwise distances, cluster analysis can find groups in data. Interestingly, special pairwise distances are an essential part of multivariate methods such as principal component analysis (Euclidean distance) and correspondence analysis (Chi-square distance).

A typical process of data clustering is demonstrated in Figure 1 with distances as a key feature. In the first row, the data matrix $\mathbf{X}$ represents objects (here: reliefs of gods of the Lion Temple at Musawwarat es Sufra in Sudan) and binary attributes (0 = absence, 1 = presence). The dendrogram visualizes the hierarchical clustering of these objects based on their pairwise distances (lower triangle of the $(I \times I)$ – matrix $\mathbf{D}$, due to

symmetry). This visualization of the hierarchy of clusters reveals at least two groups of gods, namely {27, 16, 14, 4, 26, 15, 2, 6, 5} and {10, 9, 22, 13, 12, 20, 19, 7, 18}. In the last row, hierarchical clustering of the attributes based on their pairwise distances is shown. Again, there are at least two groups of attributes, namely {V3, V2, V4, V6, V5, V10} and {V11, V12, V15, V17}.

The term distance (or dissimilarity) could have numerous meanings. The *Oxford Advanced Learner's Dictionary* defines distance as “[amount of] space between two points or places”, and it denotes distant as “(sometimes used with measurements) far away in space or time”. However, it denotes dissimilar as “(from/to sb/sth) not the same, unlike”. It is quite common to measure the distance between two points i and h on a plane with a ruler. Alternatively, if the coordinates of these points (x_{i1}, x_{i2}) and (x_{h1}, x_{h2}) are known, the corresponding (Euclidean) distance in the R^2 space is simply determined by:

$$d(i, h) = d_{ih} = \sqrt{(x_{i1} - x_{h1})^2 + (x_{i2} - x_{h2})^2} \quad (1)$$

The Euclidean distance complies with the (general) mathematical definition of a distance function.

A distance function d on a given set X (object space) is defined as $d: X \times X \rightarrow R$ (wherein R is the set of real numbers) fulfilling the following conditions ($i, h \in X$):

- (D1) $d(i, h) \geq 0$ (non-negativity)
- (D2) $d(i, i) = 0$ (distance of an object to itself is zero)
- (D3) $d(i, h) = d(h, i)$ (symmetry)

The latter means that the distance between i and h is the same in either direction. If, in addition,

- (D4) $d(i, h) = 0$ if and only if $i = h$ (principle of identity)

and d fulfils the metric (triangular) inequality ($i, h, m \in X$):

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0194

$$(D5) d(i, h) \leq d(i, m) + d(m, h)$$

then it is termed a metric distance function, or, in short, a metric. The Euclidean distance is a metric, and so it allows a geometric interpretation such as: the direct way from i to h is the shortest. Generally, given an $(I \times J)$ – data matrix $\mathbf{X} = (x_{ij})$, the Euclidean distance between objects i and h is:

$$d_{ih} = \sqrt{(x_{i1} - x_{h1})^2 + (x_{i2} - x_{h2})^2 + \dots + (x_{ij} - x_{hj})^2} \quad (2)$$

The Euclidean distance given in Equation 2 is an appropriate measure in the case of measurement data. Such a distance function maps the dissimilarity of two arbitrarily high-dimensional vectors of the space R^J as a (single) real number. Whatever the number of dimensions (attributes) J may be, the outcome is a scalar that becomes a single element of the $(I \times I)$ – distance matrix $\mathbf{D} = (d_{ih})$. Comparatively, the human eye, particularly that of the archaeologist when sorting or reordering, is capable of perceiving distances of objects in one, two, and even three dimensions, but, hardly in higher-dimensional spaces.

Figure 1 A typical application of distances in the context of data clustering. Given a data matrix $\mathbf{X}$, the clustering of the objects is based on the Jaccard distance in Equation 3 followed by the hierarchical average linkage clustering (Everitt et al. 2011). In a similar manner, the hierarchical average linkage clustering of attributes is applied on the base of the distance matrix $\mathbf{G}$ between attributes. Here the simple matching distance from Equation 4 is applied.

In applications to archaeometry, the distance measure has to be fixed very carefully for the mapping of high-dimensional vectors to a scalar. So, it may need meticulous efforts to choose an appropriate distance function for the data, because otherwise a distance function can yield misleading or even very dangerous results. First, the choice depends on the purpose of the considered multivariate statistical analysis, in other words, on the statistical model that has to be applied. Second, it also depends on the type of given data. Depending on the level of information (quantitative, categorical, binary, etc.), some of the most well-known distance measures are described briefly below.

Binary (or absence/presence or 0–1) data have the lowest level of information. Usually, the value 0 represents “false” (absence of an attribute) and 1 means “true” (presence). Oftentimes, the presence of an attribute is much more meaningful than its absence, as is the case in the archaeological data presented in Figure 1. Such an attribute is called asymmetric, otherwise symmetric. The Jaccard distance measure is a so-called non-invariant coefficient concerning symmetry with presence (=1) as the most important information. It is defined as:

$$d_{ih} = (\#_{10} + \#_{01}) / (\#_{10} + \#_{01} + \#_{11}) \quad (3)$$

where $\#_{10}$ counts the binary combination 1 (presence) and 0 (absence) of the two objects i and h across all J attributes; $\#_{01}$ counts the binary combination 0 and 1 of the two objects i and h ; and $\#_{11}$ counts the binary combination 1 and 1 of the two objects i and h , i.e., it is the number of 1–1 matches (or positive matches) across all J attributes.

Obviously, the higher $\#_{11}$ is in the denominator, the lower is the corresponding distance value. Here, the number of 0–0-matches (or negative matches) $\#_{00}$, counting the binary combination 0 and 0 of the two objects i and h , does not have any influence. Therefore, the Jaccard distance in Equation 3 is an appropriate distance measure that reflects the dominant importance of positive matches when assessing how distant any two archaeological objects are. For example, the Jaccard distance between objects 9 and 10 of Figure 1 is very small, namely $d(9, 10) = (0 + 1)/(0 + 1 + 5) = 0.167$. In contrast, the Jaccard distance between objects 10 and 27 is $d(9, 27) = (5 + 3)/(5 + 3 + 0) = 1$ (maximum). It should be mentioned that

the Jaccard similarity coefficient $s_{ih} = \#_{11}/(\#_{10} + \#_{01} + \#_{11})$ is more commonly known in statistics (Jaccard 1908), which is related to Equation 3, simply by $d_{ih} = 1 - s_{ih}$.

Other non-invariant distance measures for binary variables, for which the presence of attributes is more important, are:

$$d_{ih} = 2 (\#_{10} + \#_{01}) / (\#_{11} + 2 (\#_{10} + \#_{01})) \quad (\text{Sokal and Sneath})$$

$$d_{ih} = (\#_{10} + \#_{01}) / (2\#_{11} + \#_{10} + \#_{01}) \quad (\text{Dice})$$

The most important invariant distance measures concerning symmetry are:

$$g_{ih} = (\#_{10} + \#_{01}) / (\#_{10} + \#_{01} + \#_{00} + \#_{11}) = (\#_{10} + \#_{01}) / J \quad (\text{simple matching}) \quad (4)$$

$$d_{ih} = 2 (\#_{10} + \#_{01}) / (\#_{00} + \#_{11} + 2 (\#_{10} + \#_{01})) \quad (\text{Rogers and Tanimoto})$$

$$d_{ih} = (J - \#_{11}) / J \quad (\text{Russell and Rao})$$

$$d_{ih} = (\#_{10} + \#_{01}) / (2 (\#_{00} + \#_{11}) + (\#_{10} + \#_{01})) \quad (\text{symmetric Sokal and Sneath})$$

Clearly the Euclidean distance in Equation 2 is also an invariant measure for binary data, because it is related to the simple matching distance in Equation 4 simply expressed by $d_{ih} = (J g_{ih})^{1/2}$. That is of interest from a mathematical point of view.

Whenever the given binary data matrix contains both asymmetric and symmetric attributes, a distance value can be composed of a mixture of different distance measures, for example, the simple matching distance for symmetric situations and the Jaccard distance for the asymmetric ones. This is easily applicable since all the above-mentioned distance measures (except for the Euclidean one) are normalized in terms of their minimum (=0) and their maximum (=1).

Categorical data of attributes having more than two states—color, for example—are to be subdivided into ordinal or nominal data depending on whether there is an order of the states or not. In the case of K states, a practical simple way to deal with this is to split a nominal attribute into K

(new) binary variables. Here, each state defines its own binary variable. Then, the aforementioned distance measures can be applied to the new variables. Alternatively, distance measures based on the (original) nominal data are applicable, such as the (generalized) simple matching coefficient (Kaufman and Rousseeuw 1990). An ordinal attribute with K states looks like a nominal one, but the states, say the codes $1, 2, \dots, K$, define an order such as $1 < 2 < \dots < K$. Again, a practical way to deal with this is splitting it into K binary variables, but now in a different way in order to preserve the ordinal nature. Alternatively, distance measures for quantitative data such

as the city block distance (see below) can be applied.

The aim of cluster analysis is to find groups in data such as provenances of archaeological objects. The following example is taken from Baxter and Freestone (2006), where the complete original data matrix $\mathbf{X}$ is published. It will be analyzed hereafter. Each object is characterized by $J = 11$ attributes, namely the contents of oxides in percent. The sum of oxides of every object is 100%. The dataset of colorless Romano-British vessel glass contains two groups. Group 1 consists of 40 cast bowls with high amounts of Fe_2O_3 . Group 2 also consists of 40 objects: this is a

Figure 2 Heatmap of the Euclidean (80×80) distance matrix $\mathbf{D}$ of 80 colorless Romano-British vessel glass objects. The size of the black square in a cell is proportional to the corresponding distance value.

collection of facet-cut beakers with low Al_2O_3 . Figure 2 shows a special heatmap of the Euclidean distances between the objects. Here, the sequence of the objects in $\mathbf{D}$ is the same as in the original data matrix $\mathbf{X}$. Without any doubt, the heatmap makes clear that there are at least two clusters. Obviously, the distance between a cast bowl and a facet-cut beaker is large: see the bigger filled squares in the upper left region of the plot.

This plot can be improved significantly by ordering the objects in an optimal way and applying the Euclidean distances to logarithmic transformed data. The hierarchical minimum variance method (Ward 1963) finds the true groups without any error. Ward's method is based on the squared Euclidean distances. The reason is that merging any two objects i and h with the distance d_{ih}^2 to the cluster $\{i, h\}$ results in the within-cluster variance, which is simply $d_{ih}^2/2$.

In addition to the Euclidean distance, the city block distance between objects i and h :

$$d_{ih} = |x_{i1} - x_{h1}| + |x_{i2} - x_{h2}| + \dots + |x_{ij} - x_{hj}|$$

is one of the most well-known metrics. Both are special cases of the so-called Minkowski distance given by:

$$d_{ih} = (|x_{i1} - x_{h1}|^q + |x_{i2} - x_{h2}|^q + \dots + |x_{ij} - x_{hj}|^q)^{1/q}$$

where the parameter q is a real number larger than or equal to 1. There are a lot of other measures for metric data such as angular separation, Pearson correlation, and Canberra (Everitt et al. 2011).

A practical way to handle mixed data is converting them all into the binary form. Nominal or ordinal variables with K categories can be recoded into K (or $K - 1$ for non-dichotomous) binary variables. Continuous variables should be binned first into, say, K categorical (i.e., ordinal) variables and then recoded into K binary variables. In the case of many continuous variables, the number of binary variables will grow very quickly. Obviously, the downgrading of metric variables to binary variables means a loss of information in any case. Gower (1971) proposed a general similarity measure s that can be applied directly to mixed

data. From this similarity s , as usual, a distance measure can then be obtained simply by $d = 1 - s$.

Often, variables are measured in quite different scales such as percent, ppm (parts per million), or even ppb (parts per billion). Hence, some kind of data transformation is necessary since some distance measures such as Euclidean are not independent of the scale of measurements. Then, there is a need for appropriate data transformations in order to ensure comparability among the attributes so that the distances make sense. Moreover, data transformations such as logarithmic transformations could be applied to produce nearly symmetrically distributed variables, or to handle outliers (most extreme high values) in the data.

In the case of different scales, outliers, or long-tailed skewness of the distribution, a common approach is to transform the values for every variable into their rank values. However, the conversion of measurement data to rank order tables means losing a lot of information.

In statistics, the transformation of "raw" data (i.e., a given data matrix $\mathbf{X}$) into standard scores $\mathbf{Z}$ by $z_{ij} = (x_{ij} - m_j)/s_j$ is often recommended, where m_j is the mean and s_j is the standard deviation of variable j in $\mathbf{X}$. As a result, each new variable j in $\mathbf{Z}$ has a mean equal to 0 and standard deviation 1. Alternatively, the transformation $z_{ij} = x_{ij}/m_j$ can be applied to non-negative data (Underhill and Peisach 1985). As a result, each new variable j in $\mathbf{Z}$ has a mean equal to 1 but it has individual standard deviations s_j/m_j .

Often, the logarithmic transformation $z_{ij} = \log(x_{ij})$ is applied to data if all $x_{ij} > 0$. Otherwise, if some of the x_{ij} are zero, the transformation $z_{ij} = \log(x_{ij} + 1)$ should be applied. In the case of compositional data, a special data transformation can also be used: the so-called log-ratio transformation (Baxter and Freestone 2006). However, Mucha et al. (2008) showed that cluster analysis failed to find the true groups in the data shown in Figure 2 when the log-ratio transformation was applied.

Exploratory Data Analysis (EDA)

ESTELLE CAMIZULI

Université Savoie Mont Blanc, France

EMMANUEL JOHN CARRANZA

University of KwaZulu-Natal, South Africa

The most common approach in statistics is to test if a chosen hypothesis is true at a given probability level (see *HYPOTHESIS TESTING*). This is called confirmatory data analysis (Hoaglin 2006). When determining how to properly analyze any dataset, the first consideration must be the characteristics of the data themselves (Helsel and Hirsch 2002). Exploratory data analysis (EDA) minimizes prior assumptions and guides the choice of appropriate models for further examinations (Carranza 2009; Velleman and Hoaglin 1981). This statistical approach was developed in 1977 by John Tukey, who explained that its philosophy is to look at the data to see what they seem to be saying (Tukey 1977). In simple words, one could say that EDA is used for visualization and extraction of more substantive but less obvious information from the data. Indeed, EDA uses a wide variety of techniques (descriptive statistics (see *DESCRIPTIVE STATISTICS*) and graphical tools) for more effective exploration of a dataset. It is robust for the study of patterns, allowing us to visualize the structure of the data and to identify outliers (errors, peculiarities, or anomalies). These should be examined carefully in order to understand the dominant behavior and the unusual behavior in the data (Hoaglin 2006). EDA leads to a better understanding about what kind of advanced statistical methods should be applied to the data (Reimann et al. 2008). EDA also questions whether the scale in which the data are originally expressed is satisfactory. If not, a transformation (e.g., logarithmic) into another scale would benefit further analysis.

To summarize a dataset, Tukey (1977) recommends using descriptive statistics with the

five-number summaries based on sorting and counting. These numbers describe the data with values at selected depths: the central value is the median (Q2), the dispersion is represented by the minimum (Min) and the maximum (Max), and finally, the first quartile (Q1) and the third quartile (Q3) complete the description. The interquartile range ($IQR = Q3 - Q1$) measures the variation about the center of a distribution and is the most commonly used resistant measure of spread (Helsel and Hirsch 2002; VanPool and Leonard 2011). As the median is determined by the relative rank of the data, it is only minimally affected by the magnitude of a single observation. In most cases, this resistance to the effect of a change in value or presence of outliers is an advantageous property.

One way to visualize the five-number summaries is to use the Tukey box plot (Figure 1). A box is drawn from Q1 (also called the lower hinge) to Q3 (also called the upper hinge), crossing with a bar at the median. Two fences are defined according to their distance to the box. The first fences (inner fences) are one step (1.5 times IQR) outside the box, whereas the second fences (outer fences) are two steps (3 times IQR) outside the box. The whiskers extend to the value at each end closest to, but still inside, the inner fences (Tukey 1977). Values from the fences to either minimum or maximum are individually plotted so that data apparently straying out, far beyond the others, can be identified.

Box plots allow graphical representation of a dataset through the quartiles and thus provide information about the variation and central tendencies of data in a condensed manner (VanPool and Leonard 2011). It is a valuable tool to detect outliers, which are extreme values that can have several origins. They can be, according to Helsel and Hirsch (2002): (1) erroneous values (e.g., mistakes in measurements of an archaeological artifact); (2) observations from a population not similar to that of most of the data (e.g., data reflecting foreign provenance of some objects in a specific area); or (3) rare events from single populations that are skewed. It is very important to detect and examine outliers in order to

Figure 1 Tukey box plot used to describe a dataset with five-number summaries (Min, Q1, Q2, Q3, and Max). Whiskers correspond to the value at each end closest to inner fences. Seven categories based on the Tukey box plot and defined for mapping of geochemical anomalies are also specified.

determine if they should be excluded or treated with specific statistics. Box plots are excellent for the discrimination of properties within a dataset, even for comparisons between many groups of data. They are useful tools in determining whether medians, spreads, and symmetries differ among groups of data (Helsel and Hirsch 2002). Box plots, together with histograms and scatter plots are, among the EDA graphical tools, particularly used in any archaeological study.

Histograms provide a clear way of visualizing the frequency distribution of data in classes for a single variable (Figure 2, left). Bars are drawn with, on the ordinate, the number of data that fall into several categories on the abscissa. The histogram exhibits data structure, the central values, and the range per class. However, the visual display depends on the choice of the number of classes. The histogram permits at a single glance the detection of whether a data distribution is symmetrical or skewed. It is also readily apparent from a histogram if the data distribution is unimodal (with one peak depicting the presence of a single population) or multimodal (with several humps depicting the presence of several populations) (Reimann et al. 2008).

A two-dimensional scatter plot is an informative and simple graphic to study the relationships between variables (Figure 2, right). In EDA, data for two variables can be plotted to identify any unusual structures in the data (linear/curved, separate regions, variability in spread) and assist in determining which process could produce these unusual structures (Helsel and Hirsch 2002; Reimann et al. 2008).

Box plots are useful for comparing data for single variables, whereas two-dimensional scatter

plots illustrate relationships between two variables. However, it is also important to study relationships when there are more than two variables (which is often the case in archaeology). Several other tools/methods of EDA can provide insight into variable relationships, such as scatter plot matrix (Figure 2, center) and principal components analysis (see PRINCIPAL COMPONENT ANALYSIS) (PCA). PCA is a method to express differently the data. The PCA-transformed data are a linear combination of the original variables, uncorrelated and arranged in order of decreasing variances (Helsel and Hirsch 2002). PCA is dependent on the scale, so the transformation of data before analysis is of primary concern. This method is used to study correlations between the variables in large datasets, and to find which variables are redundant for further analysis. PCA helps to distinguish different populations and allows the identification of outliers. It is often used before a cluster analysis.

The EDA approach is widely used in various scientific domains such as environmental sciences, earth sciences, and economics, as well as in all the fields of archaeology. The work of archaeologists is indeed to analyze archaeological records (see ARCHAEOLOGICAL RECORD), behind which is the idea of describing, counting, and measuring these records, to categorize them in order to interpret function, provenance, or to a greater extent human behavior and culture (see ARCHAEOLOGICAL CLASSIFICATION). In other words, one of the archaeologist's objectives is to study the typology of artifacts through qualitative (e.g., color estimation) and quantitative (e.g., length and width measurements) variables. These typological studies can lead to the

Figure 2 Three examples of EDA graphical tools: histogram (left), two-dimensional scatter plot (right), and scatter plot matrix (center).

collection of large datasets. EDA is also useful when data are not sufficient for confirmatory data analysis, and this is important because sometimes archaeologists have to deal with limited/subset data (i.e., the study materials are only a portion of the past) (VanPool and Leonard 2011).

EDA applications in archaeological fields are numerous. EDA of the spatial distribution of chemical elements in archaeological soils helps to understand the function of specific areas. In anthropology and archaeozoology, the analysis

of morphological traits may help to study population movement. To study ceramic or lithic provenance, for example, with trace element and mineralogical analyses, archaeologists have to define potential subgroups. This can be done by combining several EDA tools such as bivariate plots, cluster analysis (see CLUSTER ANALYSIS), or compositional profile plots. These tools assist archaeologists in the first step to identify artifact composition groups and to partition a dataset into groups of samples that apparently have distinctive compositions.

An application of EDA is detailed here for the interpretation of trace metal anomalies as a tool for field prospection in mining archaeology. This case study illustrates the potential of EDA to assist explaining how geochemical anomalies in streambed sediments could help in tracing ancient mining sites. The study area is the French

northern Alps where several phases of mining occurred from the Bronze Age to the twentieth century. The mining sites are spread all over the territory and various substances were exploited including iron and lead (Figure 3, left). The exploitation of mineral deposits may considerably extend mineral dispersal, thus causing persistent

Figure 3 Inventory of mining sites in the French northern Alps (left), location of streambed sediment samples in the same area (right), and simplified map of lithological units (center).

Source: Data (geology, mines, and sediments) are from the French geological survey. Databases for the mines and streambed sediment samples are available at <http://sigminesfrance.brgm.fr/>. local trace metal anomalies. The underlying idea of this case study is that streambed sediments represent composite erosion products of terrains outcropping in the catchment area. There are thus ideal proxies for studying the spatial repartition of ancient mining sites according to geochemical anomalies.

In the 1980s, the French geological survey (BRGM) performed a national inventory of mineral substances (<http://sigminesfrance.brgm.fr/>), leading to a huge amount of geochemical data. In the French northern Alps, 6,892 streambed sediment samples were collected (Figure 3, right), sieved at 125 μm , dried, and analyzed by direct current plasma for elemental compositions. For this case study, we focus on lead (Pb) concentrations because this element is known as a persistent pollutant, causing harmful effect (Kabata-Pendias and Mukherjee 2007). Since the first evidence of mining and metallurgical activities, large amounts of metals including Pb have been emitted into the environment. Lead is known for its low mobility in the environment and can be trapped in soils and sediments for

centuries; this is thus an excellent choice to study the mining anomalies. Moreover, Pb is a chemical element commonly studied in archaeology, particularly in lake sediments or metal artifacts. The ratio of Pb isotopes is indeed used for dating, studying provenance, and identifying pollution sources.

Geological information is of prime importance as well for determining correlation of streambed sediment samples with underlying local lithology. Simplified lithological units in the study area were extracted from the 1:1,000,000 scale map of the BRGM (Figure 3, center).

The point is to determine threshold trace metal concentrations by EDA procedures so as to distinguish anomalies from the local geochemical background. Such anomalies could be related to certain lithology but also to mining activities. A transformation procedure was applied to the data before computing thresholds, to make comparable the streambed sediment samples coming from different lithological units. In short, the data were centered (subtraction) with respect to the median (*med*) and then scaled (division) with respect to

Figure 4 Pb concentrations in streambed sediments in the French northern Alps according to simplified lithological units.

Source: Original data (left) and standardized data (right) for EDA mapping (lithological data derived and modified from French geological survey 1:1,000,000 scale map). Graphics were created using R software (R 3.3.0, <https://www.R-project.org/>).

the median absolute deviation (MAD) for each lithology (j), thus:

$$Z_{Pb,j} = (X_{Pb,j} - med_{Pb,j}) / MAD_{Pb,j}$$

MAD is another resistant estimator of spread and is somewhat equivalent to the standard deviation (Helsel and Hirsch 2002). However, with the kind of transformation using the equation above, the transformed values can be negative and thus cannot be log-transformed. Another transformation was then applied to make all values greater than or equal to 1:

$$z_{Pb,j} = 1 + Z_{Pb,j} - \min(Z_{Pb,j})$$

Figure 4 illustrates the use of the above equations to standardize Pb concentrations (zPb) in

streambed sediments according to the lithological units.

Once the data are comparable, six Tukey thresholds were computed defining seven categories for EDA mapping: far and near low outliers, low background, background, high background, near and far high outliers (Table 1, Figure 1). The thresholds were calculated using the `map.eda7` function of the `rgr` package, supplementing the R software (R Development Core Team 2016).

Near and far high outliers are the two categories that are particularly interesting for highlighting ancient mining site areas. Computation shows that these categories represent 5.04 percent of the dataset (Table 1). It is easy to link each sample to the corresponding category, and, as each sample possesses coordinates, to

Figure 5 Mapping of high EDA anomalies in standardized Pb concentration (zPb), with data from streambed sediments in the French northern Alps. Also shown are Pb mining sites inventoried by the French geological survey. MP, Macôt-la-Plagne; PN, Peisey-Nancroix.

Source: The maps were created using QGIS software (QGIS Essen 2.14.6, <http://www.qgis.org>), adapted by E. Camizuli from ©IGN-2017.

Table 1 Ranges of the seven categories for EDA mapping, calculated from standardized Pb concentrations in streambed sediment samples, and their respective percentage in the whole dataset.

EDA category	Range (zPb)	Percentage
Far low outliers	≤ 0.75	0.00
Near low outliers	(0.75–1.41)	0.73
Low background	(1.41–2.65)	24.23
Background	(2.65–4.03)	49.58
High background	(4.03–7.5)	20.43
Near high outliers	(7.56–14.2)	3.34
Far high outliers	> 14.2	1.70

map them with the mining inventory (Figure 5). When focusing on an area with known mining activities, such as Macôt-la-Plagne (eighteenth to twentieth centuries) and Peisey-Nancroix (eighteenth to nineteenth centuries), it is easy to visualize their impacts. Areas with anomalies and unknown mining sites would be good candidates for prospecting if no other explanation for their presence can be found.

EDA is widely used by archaeologists to summarize and graphically display their data. These procedures and confirmatory data analysis complement each other. EDA results may stimulate further questions and lead to further analysis. If possible, data should be investigated with both approaches to avoid misinterpretation (Reimann et al. 2008).

FURTHER READING

Factor Analysis

DWIGHT W. READ

University of California, Los Angeles, USA

Factor analysis (FA), like principal component analysis (PCA), involves reducing the dimensionality of the measurement space computed over the dataset brought forward for analysis. The two differ by PCA typically being used in exploratory data analysis aimed at inferring patterning in the dataset brought forward for analysis, whereas FA involves confirmatory data analysis aimed at accepting or rejecting a model hypothesized to represent the patterning in the dataset.

Both procedures reduce redundancy in the dimensionality of the measurement space for the dataset. With archaeological data, dimensionality redundancy arises when the number of variables the archaeologist selects for measurement of artifacts over-represents the likely number of dimensions that were under control when making an artifact. For example, the projectile points from the 4 VEN39 site in Ventura County in California were measured using seven metric attributes, although it is highly unlikely that a producer kept seven dimensions in mind when making a projectile point.

With multivariate data, exploratory data analysis is often employed due to lack of adequate theories from which a model specifying the anticipated patterning in the dataset may be proposed. Dimensionality reduction also enables visual presentation of the data in the form of histograms for a single variable or scattergram plots in two or three dimensions. Both FA and PCA employ visual representation for discerning the structure of the data being analyzed.

Although dimensionality can be reduced by simply restricting the analysis to one or two variables at a time, patterning that involves several variables is then difficult to discern. Instead, dimensionality reduction is aimed at removing redundancy in the dimensionality of the measurement space for the dataset. For ratio-scale

variables this may be done with FA or with PCA. (Multidimensional scaling is used to reduce dimensionality with ordinal-scale variables and correspondence analysis does the same for nominal-scale variables, but these will not be discussed here.)

FA and PCA have the same underlying mathematical foundation for computing numerical information derived from the data brought forward for analysis that is central to these two procedures. This includes numerical information referred to as eigenvalues, component/factor loadings, and component/factor scores, depending upon which procedure is being employed (see *PRINCIPAL COMPONENT ANALYSIS*). Instead, the focus here is on the differences between FA and PCA from the perspective of exploratory data analysis versus confirmatory data analysis, so as to identify the reasons for using one technique or the other. In addition, an aspect relevant to both FA and PCA that has been insufficiently discussed in the literature, and is especially relevant to the use of FA or PCA with archaeological datasets, will also be discussed.

Reducing dimensionality involves a trade-off between, on the one hand, facilitating visual discernment of patterning, and, on the other hand, preserving as much of the numerical information embedded in the measurement space as possible. Both procedures involve (mathematically) determining a less redundant dimensionality for the measurement space as follows. Begin with a dimension corresponding to an axis in the measurement space along which variability in the data projected perpendicularly onto this axis is maximal among all possible axes for the measurement space. The next dimension corresponds to the axis perpendicular to the first axis along which the next greatest amount of variability in the measurement space occurs, and so on.

The axes are referred to as factors in FA, and principal components in PCA. Due to the way they are constructed, the first few factors in FA, or principal components in PCA, will encompass much, or even most, of the variability in the data being analyzed, thereby reducing the

dimensionality of the measurement space with relatively little loss of information. PCA and FA differ by the former being model-free and the latter model-based in the determination of these new dimensions. Being model-free means that, in PCA, as many principal components are determined as there are variables. Thus the original measurement space has simply been re-expressed with new dimensions corresponding to axes ordered according to the amount of variability in the data accounted for by each axis. In PCA, considering only the first few principal components for further analysis of the data reduces dimensionality. There are “rules of thumb” for deciding how many principal components should be kept.

Factor analysis differs from PCA by employing a model for the reduction of the dimensionality of the measurement space in which the variables being measured are deconstructed into two parts: the deterministic part and an error term. To illustrate, suppose (following the ideas of Rouse 1939) that potters first decide on the desired height of a pot and then on its diameter as a linear function of its height. However, errors in the diameter corresponding to the height occur while making the pots. We can model their ideas about these two pot dimensions by the equation $D = \alpha + \beta H + \epsilon$, where D is the pot diameter, H is the pot height, ϵ is the amount by which the actual pot diameter deviates from the potters’ normative relationship, $D = \alpha + \beta H$, and the values for the parameters α and β express the normative relationship they have in mind between H and D . If we assume that the errors in the diameter arising when making a pot are small and without directionality, then it follows that the ϵ values will tend to have a normal distribution with mean 0 (since there is no directionality) and standard deviation σ , whose magnitude expresses the care taken by the potters when making the pots.

With factor analysis, the model for dimensionality reduction expresses metric variables as being determined by factors, with fewer factors than there are variables. For example, suppose the five metric variables length (L), width (W), thickness (T), angle of the tip (A) and height of the base concavity (H) are measured over triangular-shaped, concave-based projectile points, and the archaeologist hypothesizes that three factors, size, shape, and hafting, determine

the values for these variables as follows: $L = \alpha_1 \text{Size} + \epsilon_1$, $W = \alpha_2 \text{Size} + \epsilon_2$, $T = \alpha_3 \text{Size} + \beta_1 \text{Hafting} + \epsilon_3$, $A = \gamma_1 \text{Shape} + \epsilon_4$, and $B = \beta_2 \text{Hafting} + \epsilon_5$. The model expresses how the value for each variable varies with the values of the three hypothesized factors. The model also illustrates possible variability in how factors may relate to variables: (1) a factor need not affect all of the measurement variables; (2) the same factor can affect more than one variable; and (3) a variable can be affected by more than one factor. The parameters express the hypothesized relationships that the producers “have in mind.” For each measurement variable, an error term expresses deviation in that measure due to the producer’s error when making a projectile point.

With FA, the dimensionality of the measurement space is reduced to the number of hypothesized factors. The error terms account for variability not expressed through these factors. The factors corresponding to each of size, shape or hafting is determined from the correlation (factor loadings) of the variables with the factors. According to the model, the factor corresponding to size should only be correlated with L , W , and T , the factor corresponding to shape should only be correlated with A , and the factor corresponding to hafting should only be correlated with T and H . The model is accepted only if it satisfies goodness-of-fit criteria, including the hypothesized pattern of variable-factor correlations and the assumption that the error terms tend to have normal distributions.

FA can also be used in a quasi-exploratory manner when there are no factors identified in advance and the goal is to infer possible factors determining the variable values. Here, the model will express each variable as a linear combination of the possible factors and an error term. The number of factors must be estimated, but this depends on knowing the variance of the error terms, and the latter cannot be determined unless the number of factors is known. A number of approximations have been devised to help to resolve this indeterminacy.

Once the number of factors is estimated, then the pattern of factor loadings (correlations of variables with factors) is computed and used to infer what a factor seems to measure. A commonly used procedure to help infer what are the underlying factors is to rotate the axes in the

reduced measurement space so as to obtain factor loadings as close to 0 or 1 as possible. What is conceptually common to the variables all having a loading of 1 on a factor and a loading of 0 on the other factors would, presumably, be what that factor is measuring.

Probably the most renowned attempt in archaeology to use factor analysis to determine underlying factors was the attempt by Binford and Binford (1966) to infer toolkits as the factors underlying the frequency counts for tool types (based on Bordes' typology for Mousterian stone tools) found in Mousterian sites from Europe and the Middle East. They hypothesized that a factor would be a toolkit composed of the tool types used in a particular kind of activity. The tool type frequencies in a site would then be the consequence of the frequency with which an activity associated with that toolkit occurred at a site.

Their use of FA in this manner was heavily critiqued, and the notion of determining toolkits through FA has largely been dropped. However, the criticisms mainly related to technical issues that can be resolved. But a deeper problem with most archaeological datasets affects not only the use of FA (or PCA) for inferring underlying factors thought to be the drivers of the values for the measured variables, but virtually all statistical methods.

The problem stems from the fact that when statistical methods are used inferentially rather than descriptively, there must be homogeneity in the dataset brought forward for analysis; that is, all data values must arise through the same model with the same parameter values. This assumption was violated in the factor analysis of the Mousterian data, both by including each excavation unit in a site as an independent observation, and by the assumption that precisely the same relationship between tool types and toolkits held at all sites in Europe and the Middle East.

The difficulty that arises, in general, with archaeological data is that the dataset brought forward for analysis is typically heterogeneous and so an initial analytical goal should be one of partitioning the dataset into homogeneous subsets (see Read 2007; 2014) that are then to be used in further analysis. The problem with using heterogeneous data when inferring factors (or principal components) is illustrated in Figure 1, where the factors for the dataset as a

Figure 1 Heterogeneous dataset consisting of five subsets. Factors (dashed lines) for the dataset as a whole correspond neither to the factors for each of the subsets (dotted lines) nor to these subsets being one-dimensional. Subset A: diameters decrease with height. Subsets B–D: diameters increase with height in the same manner. Subset E: no relationship between diameter and height.

whole do not correspond to the factors computed on each subset separately. Thus the factors derived from considering the dataset as a whole may not have any archaeological meaning, contrary to the rationale for conducting the factor analysis.

The factors determined through FA or inferred through PCA assume homogeneous datasets with regard to the posited factors, hence the need to subdivide a heterogeneous dataset into homogeneous subsets with respect to the posited factors. However, transforming a heterogeneous dataset into homogeneous subsets incurs the “double-bind” problem discussed in Read (2014), since the criteria used to identify homogeneous subsets depends on already knowing the dimensions along which heterogeneity occurs, except in low-dimensional measurement spaces for which visual methods such as histograms or scatter-gram plots may be used to detect heterogeneity visually. For higher dimensional measurement spaces, ways to resolve the double-bind problem are discussed in Read (2007; 2014). The problem with heterogeneity of the data making up the dataset brought forward for analysis is common to all statistical methods in which the goal is inferential and not just descriptive.

Fractal Models

ALEKSANDR DIACHENKO

Institute of Archaeology of the National Academy of Science, Ukraine

Fractal models are used to describe complex objects of irregular shape and nonlinear dynamic systems in physical and social spaces. Since these objects and systems have non-Gaussian statistical properties, the related studies require more sophisticated approaches (see POISSON AND BINOMIAL DISTRIBUTION AND STATISTICS IN ARCHAEOLOGY). Over the last 50 years, fractal models have been intensively applied in scientific fields including mathematics, physics, economics, biology, geomorphology, geography, computer sciences, cosmology, medicine, spatial demography, and linguistics. They may be applied to describe a wide range of structures and processes, from rocks and spatial perimeters to the turbulence and dynamic behavior of markets.

Introducing the term *fractal* into scientific circulation, Benoit B. Mandelbrot derived it from Latin *fractus*, meaning *fragmented* and *irregular*. Mathematically it is defined as a set for which the Hausdorff dimension strictly exceeds the topological dimension (Mandelbrot 1983). The Hausdorff (or fractal) dimension (D), the major statistical property of fractals, is estimated as follows:

$$D = \frac{\log p}{\log s}$$

where p is the number of self-similar portions and s is the scaling ratio of the portion to the whole. Any set with a non-integer dimension is a fractal. However, some examples of fractals with an integer dimension are also known (Mandelbrot 1983).

Since this mathematical definition is usually difficult for a wider audience, including social scientists, to understand, fractals are often introduced by their most important properties. Being scale-invariant and self-similar, a fractal as a whole may be studied through the analysis of

its portion. However, in numerous cases similarity between the smaller and larger portions does not mean that the former is just composed of scaled identical copies of the latter, or vice versa. Mandelbrot suggested the distinction for self-similarity and self-affinity defined as, respectively, invariance in changes in size or invariance in more than one scaling factor.

The scaling relationship in the size of portions of a fractal (p) is expressed by the power law function:

$$f(s) = kp^a$$

where k is the normalizing coefficient and a is the exponent that describes the behavior of a system; k and a are the constants. The smallest value of p , the initial point of the growth of a fractal, is called the initiator, while the power law function, the algorithm producing this growth, is called the generator (Mandelbrot 1983). In the case of self-affine variations, the structure of their outcome, called a multifractal, is operated by more than one power law function.

It should be noted that the scaling relationships expressed as power laws, also known as allometric growth models or Horton ordering process, were observed and applied to models describing the distribution of quantities in the physical and social spaces independently of Mandelbrot's work. Initial studies also questioned the similarities and differences between fractal relationships observed in physical and social systems. This early work may be exemplified by the size–frequency distribution of urban population, known as Zipf's law, or the magnitude–frequency distribution of earthquakes, known as the Gutenberg–Richter law.

Behavior in some complex dynamic systems combines the properties of chaos, or the highly sensitive dependence upon initial conditions, and fractals. The most widely known examples of this are the self-organized criticality and bifurcation diagram of the logistic map. Self-organized criticality is a property of complex dynamic systems that are driven to critical states or phase transitions (transformation of the properties of a system) by their internal

DOI: 10.1002/9781119188230.saseas0248

development alone. In these instances, no external inputs are required. Fractals, including the aforementioned models for the distribution of earthquakes and urban populations, can be viewed as an outcome of intermittent phase transitions within a self-organized dynamic process (Bak 1996). Robert May and Mitchel Feigenbaum, in the fields of theoretical ecology and theoretical physics, respectively, independently investigated the complex behavior derived from the first-order difference equation of the so-called logistic or S-shaped growth. Such growth is characterized by a transition from simple periodic behavior to aperiodic regimes of growth with period doublings. This model describes the behavior of numerous complex dynamic systems, including population growth.

Research on fractals in archaeology and anthropology was pioneered by Ezra B. W. Zubrow (1985). Providing a theoretical and methodological framework for the new ideas exemplified by the case studies, he suggested five broad areas for the application of fractal models to archaeological records:

- Measurement of structures that cannot be distinguished from one another topologically, including the parameters of artifacts (see *ARCHAEOOMETRY*). Considering fragmentation as an inherent property of archaeological data (see *MATERIAL CULTURE*), application of fractal models allows for filling gaps in information derived from the sampled data (see *SAMPLING THEORY*).
- Simulation of complex phenomena, including the evolution of culture.
- More precise description and interpretation of the perimeters of spatial objects.
- Re-assessment of the application of well-known spatial models developed in analytical geography, such as Central Place Theory, nearest neighbors analysis, and the rank-size rule (see *SPATIAL ANALYSIS*), to archaeological records within a context of non-Gaussian statistics.
- The ability to deal with complex patterns, including applying fractal algorithms to the measurement of complexity.

Subsequent studies in these areas resulted in significant achievements, while the large number

of related research reports already necessitated extensive literature reviews at the beginning of this century. The topics highlighted by Zubrow are also closely related to the field of network analysis, which has been widely applied to archaeological data in recent years (see *NETWORK SCIENCE*). Particularly, the statistical properties of scale-free networks are described by the power law function (see Bentley and Maschner 2003 for overviews and case studies).

Fragmentation of artifacts, such as ceramics and tools made of flint and stone, showcase fractal properties (see *POTTERY DATA QUANTIFICATION* and *LITHICS DATA QUANTIFICATION*). For instance, the size–frequency distribution of pottery sherds and unbroken vessels, as well as flakes and tools made of flint and obsidian, is expressed by the power law function (see Brown, Witschey, and Liebovitch 2005; Zubrow 1985). This property is also found in the distribution of the volume of pottery. Application of fractal models to sets of artifacts extends the number of statistical tools used to simulate the intensity of artifact use and discard rates; this enables estimation of the number of pots or flint tools that were in use contemporaneously, leading to new perspectives on production and distribution (see *POTTERY DATA QUANTIFICATION*). This also provides a non-Gaussian way of estimating the level of repetitiveness of a sample in relation to the whole system (see *SAMPLING THEORY*), while also linking the analysis of initial archaeological data with the overarching economic and demographic phenomena.

Fractal properties are noted for the shapes of certain objects of monumental architecture (for example, pyramids) and settlement patterns, including the Ancient Maya cities. Since many features of the landscape, including geological structures and river networks (see *RIVER SYSTEMS*) are also fractals, the related analysis of settlement systems provides new perspectives on understanding human–environment interactions (see Brown et al. 2005; Zubrow 1985).

Fractal models are also applied to the developmental dynamics of social phenomena of the remote past. Some examples of these phenomena are culture change and evolution, stasis and avalanches in social and cultural development, interactions at different spatial scales, emergence of inequality, and ancient subsistence strategies

(see Barceló and Del Castillo Bernal 2016; Bentley and Maschner 2003; Brown et al. 2005 for the overviews and case studies). Work related to fractals includes the concept of self-organized criticality and the associated theory of punctuated dynamic equilibrium, hence contributing to method and theory in archaeology. In punctuated equilibrium, relatively long periods of stasis are interrupted by rapid bursts. These interruptions occur at critical points, where even small-scale disturbances can result in systemic imbalances (Bak 1996; Bentley and Maschner 2003). Therefore, the system state has to be considered in simulations and analysis of causal relationships between events.

Since the empirical basis for the fractal-like distribution of population has a long research history, the significant achievements of recent studies on population structure and land use are not surprising (see PALEODEMOGRAPHY and HUMAN POPULATIONS). For instance, Marcus J. Hamilton and his co-authors (2016) use fractals to demonstrate that social complexity emerges as early as in hunter-gatherer groups. Size of groups and population density follows the power law function. Moreover, a scaling ratio was found for hunter-gatherer spatial utilization, indicating that the size of the catchment area required by one person decreases as population density increases. Increasing density is further associated with a trend of decreasing annual movement. These results not only provide us with a mathematical description for the increase in complexity in relation to the balance between subsistence strategies, collaboration, and spatio-demographic structure of hunter-gatherers, but also allow for a hypothesis considering the transition to sedentism as a result of changes in subsistence ecology, rather than an increase in the number of people and population pressure (Hamilton et al. 2016).

DeLong and Burger (2015) consider population as a proxy for the total amount of energy produced by socioeconomic organization and environmental conditions that is consumed by human groups. According to their results, values of the exponent in the power law function that are lower than 1 characterize density-dependent growth, limited by a constant resource supply. Values approximately equal to 1 indicate exponential growth, while values exceeding 1 denote

super-exponential growth (DeLong and Burger 2015). Hence, the values of the exponent in the power law function represent a proxy for the increase or decrease in complexity.

As the majority of overviews on this topic remind us, despite the numerous fractals that are known, objects and systems of physical and social space have different statistical properties, and fractal models are applicable only to a part of them. However, measurement and explanation of those objects and systems that do exhibit non-Gaussian properties require the use of non-Gaussian statistical tools that have significant descriptive and analytical potential (see SAMPLING THEORY and STATISTICS IN ARCHAEOLOGY). Further work on fractal models in archaeology and anthropology opens new research perspectives on long-term development (see TIME AND TEMPORALITY), separating individual trends and general trajectories that appear to be far more complex than previously thought. These models yield fruitful results when they are used to explain the distribution of artifacts and their fragments, and may be applied to other problems connecting spatial objects to wider sets of data. This is also true for studies in population structure (see HUMAN POPULATIONS) and land use. Fractal modeling and the outcome of its applications has yet to be deeply integrated into archaeological method and theory.

Geometric Morphometrics

P. DAVID POLLY

Indiana University, USA

Geometric morphometrics are a class of multivariate methods for measuring and analyzing the shapes of objects. Geometric morphometrics are distinctive in that they use Cartesian coordinates (x , y , z) of landmark points in place of linear measurements as variables (Bookstein 1991). Most geometric morphometric methods use Procrustes superimposition to remove scale, rotation, and translation from the coordinates, which eliminates confounding effects of size, but which limits analyses to rigid objects. A wide range of multivariate statistical tests can be employed to assess the relationship of shape to other variables of interest (Dryden and Mardia 1998). One of the most popular features of geometric morphometric methods are that analytical results can be presented visually as deformations of objects instead of as tables of numbers.

Methodology

The hallmark of geometric morphometrics is that points on the surfaces of objects (or in their interiors, if volumetric data such as CT or MRI scans are available) are used to represent their shape. For example, the shape of a square might be represented by points at its four corners, or a Paleolithic hand axe might be represented by a series of points traced around its perimeter (see Figure 1a). The points may be two-dimensional (2D) or three-dimensional (3D), producing two (x , y) or three (x , y , z) variables respectively per point. In any one analysis, the same number of points must be placed on every object in corresponding locations and in the same order.

Three strategies for placing points can be distinguished. Landmarks, in the strict sense, are single points, each of which represents the position of a particular structure. For biological objects,

landmarks are usually placed at biologically homologous positions such as the junction between three bones or the openings of foramen (see Figure 1a, large circles). Landmarks can also be placed geometrically, for example at the point of maximal depth of the mandibular ramus. Semilandmarks are series of points arranged geometrically on a structure. Edges or curves can be represented by a string of semilandmarks, traced like a dotted line around them (see Figure 1a, small circles), and surfaces can be covered with a three-dimensional grid or cloud of semilandmarks. Like with landmarks, the ordering of semilandmarks on each object must correspond. For example, the 100 semilandmarks on the hand axes in Figure 1 all start at the midline of the base and trace the perimeter clockwise. Semilandmarks can be placed at regular intervals, or their placements can be optimized by sliding them until the shape differences between objects is minimized, a strategy known as “sliding semilandmarks” (Gunz, Mitteroecker, and Bookstein 2005).

Regardless of which point-placing strategy is used, point coordinates must be registered in a common coordinate system before analysis can proceed. Most geometric morphometric methods use generalized *Procrustes superimposition* to register coordinates (Rohlf and Slice 1990). In Procrustes superimposition, the coordinates of all objects are scaled, translated, and rotated to minimize the shape differences between them. Each object is centered on the origin ($x=0$, $y=0$, $z=0$), scaled so that the squared distances between each point and the origin sum to 1 (which is known as *unit centroid size*), and the objects are rotated about the origin until the *Procrustes distance*, or sum of squared distances between corresponding points between two objects, is minimized. This least-squares-fitting algorithm ensures that differences in shape are minimized or, in other words, that they are not due to spurious differences in orientation within the coordinate system, which is an important prerequisite for applying statistical tests for differences in shape. Procrustes superimposition has the statistical consequence of reducing the

Figure 1 (a) Paleolithic hand axe with 60 semilandmarks placed at regular intervals around the perimeter (small circles) and two landmarks at the midline of the base and point (large circles). (b) The first two dimensions of a principle components analysis of the Procrustes superimposed coordinates of three hand axes. Axe 1 is the tool shown in (a). (c) A thin-plate spline diagram showing the shape difference between Axe 2 and Axe 1 as a deformation of the coordinates of the former into the latter. Modified from Smith, 1912.

degrees of freedom in the data by removing the effects of scale, translation, and rotation. Two-dimensional data are left with $2k-4$ degrees of freedom, where k is the number of landmark points, and three-dimensional data are left with $3k-7$ degrees of freedom. If the number of objects (n) in the analysis is less than these expectations, then the number of degrees of freedom is $n-1$.

Once superimposed, Procrustes coordinates are usually transformed into *shape variables* for further statistical analysis. Ideal shape variables are equal in number to the degrees of freedom and are orthogonal to (uncorrelated with) one another, but preserve shape differences between objects. The most common kind of shape variables are principal components (PC) scores (see Figure 1b). When based on the covariance method, principal components ordination represents a rigid geometrical transformation of objects to a new set of orthogonal axes whose number equals the statistical degrees of freedom of the data set. The coordinates of objects in the PC space, which are known as scores, are the shape variables. For example, the scores of Hand Axe 1 in Figure 1b are -0.08 on PC 1 and 0.00 on PC 2. Another commonly used shape variable are the *partial warps scores*, which are derived from an ordination of specimens based on the so-called bending energy matrix derived from spatial differences in the locations of points on the objects.

The principal components space is often viewed as a *morphospace*. Each point in the

multidimensional morphospace corresponds to a particular configuration of landmarks. Objects are placed at a given point when their shape corresponds to its particular configuration. Distances between objects in the morphospace are equal to the Procrustes distances between their superimposed landmark points if measured as a Euclidean distance calculated from the full set of PC scores. Principal component shape spaces are sample dependent in that their coordinate system is centered on the mean shape (the shape configuration represented by the point at the origin of the PC axes is the arithmetic mean of the Procrustes superimposed coordinates) and in that the first PC is oriented along the major axis of variation in the sample. If new objects are added, the distance between objects does not change, but the ordination of the axes and the values of the scores do.

Statistical tests and other kinds of analysis are performed on the matrix of shape variables. For the most part, any kind of multivariate statistical method can be applied to shape data, so long as the implications of the loss of degrees of freedom are taken into account (Dryden and Mardia 1998). Multivariate regression can be used to assess the relationship between shape and a continuous variable. For example, age-dependent changes in skull shape would be assessed by regressing shape scores derived from landmarks of the skull onto the chronological age of the individuals in the analysis. Multivariate analysis of variance (MANOVA) can be used to test for differences

between groups. For example, MANOVA can be used to test hypotheses that morphology is sexually dimorphic or that a new fossil sample is distinct from previously described species. Because shape variation often fails to meet the assumptions of traditional parametric statistics and because sample sizes in anthropology are often necessarily unbalanced, non-parametric permutation and Monte Carlo tests are to be preferred for shape analysis. When the objects being analyzed belong to more than one biological population or species, phylogenetic comparative statistical methods should be considered (Harvey and Pagel 1991).

Because the values of PC shape scores are sample dependent, it is perilous to try to interpret the causal relationship between just one principal component and an external factor (Polly and Motz 2016). For example, the arrangement of species along PC 1 in a shape analysis of tooth shape in monkeys may appear to correspond to the proportion of vegetation in their diets, but it is unlikely that the true relationship between tooth shape and diet corresponds precisely to that axis. Instead, a fully multivariate regression technique that utilizes the full set of shape scores from all PCs should be employed, not a visual inspection (or even a statistical analysis) of just one or two PCs.

Visualization techniques

Because shape variables directly correspond to Cartesian coordinates of points on objects, results from geometric morphometric analysis can often be presented as graphical depictions of the objects themselves. The difference between the shape of two objects, for example, can be illustrated as the displacement of landmark points. Interpolation methods such as *thin-plate splines* can use the landmark displacements to deform a grid in order to represent the deformation of one shape into another, a technique that has become one of the hallmarks of geometric morphometric methods (Bookstein 1991). For example, Figure 1c shows the difference between hand axes 1 and 2 as a thin-plate spline grid deformation of axis 2 into axis 1, which requires compression around the distal end to produce the latter's tapered outline.

While this example is applied to two objects, the same strategy can be used to show the difference between two group means (e.g., shape differences between sexes). Thin-plate spline grids are most effective with two-dimensional data. Results for three-dimensional data are often shown as animations of the change in shape along a linear trajectory through morphospace. Results from multivariate regression can be depicted the same way since the slope and intercept parameters it produces describe a line through morphospace.

History of geometric morphometrics

Geometric morphometric methods in the strict sense were first described in the late 1980s and early 1990s. Multivariate ordination and statistical methods had already been common since the 1960s (e.g., Blackith and Reyment 1971) and were applied to matrices of data such as linear measurements, angles, and areas. Statistical analysis of relationships between shape and other variables was possible using these methods, but interpretation could be difficult because size and shape were comingled and because the mapping of results onto biological form was usually interpreted by visual inspection of loadings of variables onto statistical factors. In a conscious attempt to capture the graphical power of the qualitatively estimated deformation grids that D'Arcy Thompson popularized in his book *On Growth and Form* (Thompson 1917), Fred Bookstein and others began experimenting with *truss analysis* of linear measurements that systematically connected landmark points in order to be able to transform factor loadings into a graphical map of which parts of the shape contributed most to differences between objects. The breakthrough came with the realization that Cartesian coordinates could be substituted for linear measurements and that thin-plate spline interpolations could then be used to produce deformable grids (Bookstein 1991). The addition of Procrustes superimposition as a tool to minimize shape differences as a prerequisite for statistical analysis (Rohlf and Slice 1990) completed the "geometric morphometric revolution."

Shortcomings

While geometric morphometric methods have many advantages over measurement-based methods, including the ability to mathematically factor out size and the ease with which results can be depicted graphically, they also have stubborn limitations.

Arguably the most constraining limitation is that the methods can only be applied to rigid objects. For the relative positions of Cartesian coordinates to be meaningful, each point used in an analysis must occupy a fixed position relative to all other points. The consequence is that objects that have mobile relationships to one another, such as mandible and cranium or body and limbs, cannot easily be analyzed with geometric morphometrics because spurious differences in their relative positions contribute to shape differences (e.g., the same individual would have a different “shape” if the limbs were moved to new positions). Special techniques such as two-block partial least squares can be used to analyze covariation in shape between objects that are not fixed, such as mandible and cranium, but these become cumbersome for systems involving more than two elements.

Another limitation is that the displacements of landmark points estimated by geometric morphometric methods are *relative*, not absolute, because of Procrustes superimposition. Consequently, it is impossible to localize which parts of a shape have changed. This issue has been exemplified by a thought problem involving the fairy-tale puppet Pinocchio, whose nose grew every time he told a lie. The only change in the shape of Pinocchio’s profile would be elongation of his nose; however, Procrustes superimposition distributes the differences across all landmarks because of the centering and minimization components of its algorithm. Geometric morphometrics can accurately recover the fact that the relationship between the nose and the rest of the head changed, but it would not be able to distinguish between growth of the nose, shrinking of the head, or an intermediate combination of the two. Alternative methods like Euclidean distance matrix analysis (EDMA), which is similar to the truss analysis described above, have been developed

specifically to localize which parts of a shape are changing.

Applications in anthropology and archaeology

Geometric morphometrics have been applied to many problems in anthropology and archaeology. The techniques are heavily used in evolutionary paleoanthropology, where they have been used to test for shape differences between putative hominin species, to statistically test hypotheses about functional relationships between morphology and factors like diet or sex, and to reconstruct ancestral morphologies using tip taxa and phylogenetic trees. Geometric morphometrics have also been applied to human-produced objects such as stone tools and floor-plan configurations of structures such as fortification towers and tipi rings, as well as to objects as varied as geographic topography and footprint outlines.

Future directions

The ease with which three-dimensional data can be obtained with laser scanners, computed tomography (CT) scanners, magnetic resonance imaging (MRI), and Lidar, have increased the demand for geometric morphometric analyses of fully three-dimensional surfaces. At the same time, they have exposed the shortcomings imposed by the requirement that all objects in a geometric morphometric analysis must have the same number of points in the same topographical configuration. Only a few algorithms exist for placing semilandmarks on three-dimensional surfaces and all of them are expensive in terms of the work and computational power required to implement them. The greatest advances in geometric morphometrics over the next decade are likely to be in automated algorithms that match surfaces and apply point grids. Some recent advances even suggest the demise of geometric morphometrics as we know it, in favor of strategies that map surfaces onto one another using pure mathematical functions instead of landmark points.

Human Populations

ANDREW T. CHAMBERLAIN

University of Manchester, UK

A population is a bounded group of individuals, defined biologically by their elevated probability of mating with members of their own population and, in most cases, defined culturally by their shared linguistic, social, and historical experiences. In human populations, biological and cultural parameters are closely intertwined—for example, social concepts of ancestry and kinship often condition mating opportunities, and economic circumstances influence decisions about migration and reproduction. Each individual in a population has their own distinct life history, and this gives rise to variation among the members of the population in the extent and timing of their participation in population processes and events such as birth, reproduction, and mortality. Nonetheless, the population as a whole can be characterized by parameters that together determine population structure and dynamics (change through time). These parameters are age- and sex-structured and capture rates of fertility, mortality, and migration. In some instances, these parameters are relatively invariant through time, at least at the scale of the whole population, leading to the establishment of a stable population structure. In other instances, heterogeneity in space and time are observed, for example during colonization processes and during mortality crises precipitated by epidemic disease, natural disasters, or conflict. Populations also exhibit the long-lasting effects of previous demographic events; for example, recent episodes of population expansion can result in a star-like pattern of haplogroup clusters in genetic data.

A key question in demography is whether historical and ancient populations were fundamentally different from the populations of the present-day. Historically recent changes in nutrition, hygiene, medical treatment, and fertility

control have resulted in major transformations of the fertility and mortality experience of many modern westernized populations. The “demographic transition” refers to a repeatedly observed pattern of demographic change in which populations, typically over a period of a few generations, move from a state of high fertility and high mortality to one of low fertility and low mortality, with consequent increases in average life expectancy at birth (Kirk 1996). Although there are often marked differences between ancient and modern populations in their fertility and mortality experience, some life-history variables, such as lifespan (maximum longevity) and the ages of onset of anatomical and physiological senility, show little change from the earliest periods of history to the presentday (Chamberlain 2006). An important assumption in modeling ancient populations is that some of the properties of presentday populations, including those of ethnographically censused foraging and subsistence farming communities, can be expected to have been a feature of past populations as well.

Ancient populations were responsible for generating a range of durable material residues that can be retrieved from the archaeological record, including the skeletal remains of deceased individuals, the remains of houses, settlements, and modified landscapes, and assemblages of artifacts and other materials that accumulate during resource usage. This means that a variety of different kinds of archaeological data can be used as proxies for individuals and communities in order to reconstruct the size and structure of past populations. Mortality profiles can be estimated from human skeletal remains, and this information can be combined with the duration of cemetery usage to estimate the size of the living “contributing” population (see PALEODEMOGRAPHY). House floor areas, the spatial extents of settlements, and the productivity of site catchment areas can all be used as independent variables in formulas for estimating population sizes, although it should be noted that there is considerable variation in the spatial density of human settlements. For a given mode of subsistence, the level of consumption

DOI: 10.1002/9781119188230.saseas0470

of resources can be estimated indirectly from quantities of deposited food residues, counts of artifacts, and other measures of production and usage (Schacht 1981). Demographic temporal frequency analysis uses radiometrically dated instances of human activity as a measure of the magnitude of human occupation through time (Williams 2012), and this technique has been applied extensively using summed calibrated date probability distributions to investigate regional and continental-scale changes in population size (see Goldberg, Mychajliw, and Hadly 2016 for a recent example).

Genetic evidence (see DNA: MITOCHONDRIAL; DNA: NEXT GENERATION SEQUENCING; GENETICS: ANCIENT; and GENOMICS: ANCIENT) from both modern and ancient DNA sequences provides important information about past population events including migration, colonization, and episodes of population growth and decline. Recent rapid population growth may result in a narrow distribution of pairwise differences between the DNA sequences of individuals, with their lineages clustering in star-like topologies originating from a common ancestral sequence. Comparisons of variation in sex-specific DNA haplogroups can reveal sex differences in migration rates, while measures of genetic diversity can be used to investigate variations in effective population size.

Mathematical population models are used to analyze the effects of variation in mortality and fertility on population structure and to predict patterns of population growth and decline. The effects of age-specific variation in mortality can be modeled using survival analysis, either using discrete age categories in a life table (see LIFE TABLE ANALYSIS) or by fitting mortality to a continuous

function of age as a hazard function (see PALEODEMOGRAPHY AND HAZARDS ANALYSIS). The Leslie matrix is a discrete age-structured model incorporating both fertility and mortality that can be used to predict population growth and changes in population structure. Agent-based models can also be used to explore the effects of mating rules and resource distributions on population dynamics and are a useful tool for exploring the effects of individual behavior on population-level outcomes.

Human Skeletal Data Quantification

LYLE W. KONIGSBERG

University of Illinois at Urbana–Champaign, USA

Because human skeletal data ultimately involve some form of counting or measuring, they are inherently quantitative. This entry is concerned with the various ways in which scholars and researchers quantify skeletal data. In some cases, these data are quantified as simple counts for binary variables such as male versus female, presence versus absence of discrete traits (see DISCRETE TRAITS), or under versus over age 30 years for those who die above age five years (Buikstra, Konigsberg, and Bullington 1986). In other cases, data are given as counts within ordered classes, such as the number of skeletons within each age class for a life table (see LIFE TABLE ANALYSIS) or the number of skeletons that fall within ranked severities of paleopathologies. Some categorical data have no inherent ordering, for example, counts of numbers of crania within different classes of cranial shaping (see CRANIAL SHAPING) or fronto-occipital, annular, and lamboid flattening. Though one can argue that there are rankings of amount of cranial shaping within each category, the three categories themselves are unordered.

As stated above, for categorical data the quantification is given as counts within categories. How those counts are analyzed depends on the nature of the data as well as on the possible relationships of the categorical data to other variables. For example, in a life table, which consists of ordered age classes, one would typically use the counts to estimate survivorship or age-specific probabilities of death. For counts within cranial shaping categories, compositional data analysis (see COMPOSITIONAL DATA ANALYSIS) would be appropriate. For multiple categorical variables, a simple listing of counts within classes for each variable is insufficient if the variables are not independent. For example, if cribra orbitalia, porotic hyperostosis, and sex are scored as binary

variables, the counts should be presented in a 2-by-2-by-2 table. This is because cribra orbitalia and porotic hyperostosis are both considered to be skeletal markers related to anemia (see ANEMIA), while the sex of an individual is generally not independent of the risk of developing anemia. If there is no interaction among these variables, then the various margins of a cross-classification can be analyzed separately. This is because the marginal counts can always be obtained from the cross-classification. But conversely, a cross-classification cannot be reconstructed from marginal counts. Similarly, counts in “collapsed scorings” are much less useful than counts in the original scoring because the latter cannot be reconstructed from the former (Konigsberg, Frankenberg, and Liversidge 2016).

When the data from a single classificatory variable are considered against a continuous variable it is not possible to summarize the data using counts. Instead, researchers will need access to the raw data if they wish to make their own analyses. For example, in “transition analysis” (see ESTIMATING ADULT AGE: TRANSITION ANALYSIS) for estimating adult ages, one first needs to do a quantal analysis, such as probit or logit analysis (see QUANTUM ANALYSIS), to find the parameters for the transition model. If ages are in yearly categories, counts in a cross-classification of stages against age are sufficient summary of the data to estimate the transition parameters. But if age is given in decimal years (as it should be for a documented collection with birth and death dates), then researchers will need access to the raw data on stages and ages if they wish to make the analyses themselves.

If human skeletal data originate from a continuous variable, quantification can proceed by presenting summary descriptive statistics (see DESCRIPTIVE STATISTICS) for parametric analyses. These summary statistics should be given in a scale that is appropriate for the data. For example, if the data follow a normal distribution, then the mean and variance in the raw scale as well as the sample size give a complete description of the data for further analysis. In this case, there are three summary statistics. If the data are

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0310

instead log-normally distributed, then the mean and variance should be given in the logarithmic scale. Again, this will amount to presenting three summary statistics. But if more complicated distributional forms are necessary, there will be more requisite summary statistics. For example, if the data can only be fit by a skew exponential power distribution (DiCiccio and Monti 2004), then five summary statistics are necessary, these being the location (mean), scale (standard deviation), two shape parameters, and the sample size. Assuming that the individual variables are normally distributed and that jointly they are multivariate normally distributed, the requisite summary statistics are the vector of means, the triangular part of the variance–covariance matrix, and the sample size. The triangular part of the variance–covariance matrix is the main diagonal, containing the variances, and all of the unique covariances above (or equivalently below) the main diagonal. For p variables this amounts to $p(p-1)/2$ parameters, which together with the p means and the sample size makes $(p^2+3p+2)/2$. Unfortunately, there is a long history in biological anthropology of publishing tables of sample sizes, means, and standard deviations while ignoring covariances or correlations. Konigsberg (1991) noted in regard to publishing complete summary statistics that failure to do so limited future researchers from reanalyzing data. In this era of making raw data available for download, the necessity for publishing summary descriptive statistics is potentially lessened. With that said, if neither raw data nor the requisite summary descriptive statistics are available, then publications become static references not necessarily amenable to reanalysis and further insights.

When there is further structure to the data, the number of necessary summary descriptive statistics will grow. For example, in a biological distance analysis (see BIOLOGICAL DISTANCE) between two groups, one will need the sample sizes for both groups and the vectors of means for both groups. Ordinarily, one can assume that the pooled within-group variance–covariance matrix is a reasonable representation for both groups, so that only the triangular part of one variance–covariance matrix is necessary. However, if one provides the triangular part of the variance–covariance matrix for each group, then the pooled matrix can be calculated. If only the

pooled matrix is provided, there is no going back to the original within-group matrices.

Any of the traditional univariate and multivariate statistical approaches, such as analysis of variance and covariance (see ANALYSIS OF VARIANCE AND COVARIANCE), factor analysis (see FACTOR ANALYSIS), linear models (see LINEAR MODELS), and principal component analysis (see PRINCIPAL COMPONENT ANALYSIS), can proceed from summary descriptive statistics, but in the case of specialized analyses such as those related to cross-sectional geometry (see CROSS-SECTIONAL GEOMETRY) or geometric morphometrics (see GEOMETRIC MORPHOMETRICS) the summary of data becomes more complicated. The complication arises because of the fact that geometry is involved in both forms of analysis. For the analysis of cross-sectional geometry of bones the raw data usually come as graphics image files. These can be reduced to black and white, typically with the bone in white. This reduces file size, but further reduction can be achieved using edge detection to record the pixel numbers for boundaries. Even these data are excessive and can be reduced by extracting elliptic Fourier coefficients. Elliptic Fourier reduces the perimeters to a series of harmonics that represent ellipses. Each harmonic consists of four coefficients and there are also two terms to represent the translation from the original coordinates to the center of the ellipses at 0,0. These coefficients can be used to draw the original perimeters. Because ten harmonics are usually adequate to capture the form, there are 42 coefficients to represent the outer perimeter of the bone and 42 to represent the inner perimeter. This is a substantial reduction from having to list every pixel in the traces.

In geometric morphometry the raw data consist of point locations in two or three dimensions. The data could be, for example, digitization of cranial landmarks in a craniometry (see CRANIOMETRY) study. Such digitizations are often referred to as “archiving the form” because one can extract traditional caliper-based measurements (as inter-landmark distances), but one can also analyze the landmark data directly as well as plot the average form. From the standpoint of “archiving form,” it is unfortunate that standards for data collection in advance of repatriation (see REPATRIATION) of human skeletal remains

were promulgated at a time when geometric morphometric methods were not widely available. If raw landmark data are available, then the most concise way to present summary descriptive statistics for this form of data follows from what is known as a generalized Procrustes analysis (Zelditch, Swiderski, and Sheets 2012). In such an analysis each form is translated so that its center is at the origin, it is scaled so that all forms have the same size, and then they are rotated so that the sum of squared distances between each landmark and the average landmark across forms is minimized. After this shape analysis each form can be scaled back to its original size. The average form is then literally the average landmark coordinates across the forms, while variation in landmark positions is expressed in the variance-covariance matrix of what are known as Procrustes residuals. The sum of these squared residuals across all forms and the sample size are the two final summary descriptive statistics. If k is the number of landmarks and m the dimensionality (either two for 2D or three for 3D), then the number of summary descriptive statistics is $km + km(km-1)/2 + 2$, where there are km means, $km(km-1)$ variances and unique covariances, with the sum of squared residuals and the sample size as the last two statistics. For example, ten landmarks in three dimensions for any number of crania can be described using 467 numbers.

Ultimately, researchers must make a decision whether to provide their raw data or whether to only provide summary statistics. With the increasing use of digital raw data archives, the

possibility for making such data available to others is a very real possibility. Indeed, most granting agencies now require a “data access plan” to cover the eventuality of public access to data. In the absence of such plans, researchers do need to minimally make the summary statistics available in useable form. There are unfortunately far too many publications from human skeletal biology that use and analyze multivariate data while only providing univariate summaries for the constituent variables.

Hypothesis Testing

GEOFFREY A. CLARK and
DAVID R. ABBOTT
Arizona State University, USA

Although part of the physical sciences for more than 200 years, hypothesis testing in archaeology is a relatively recent development. It arose in the 1960s, as a reaction to the limitations of the culture history paradigm that had dominated the field since its inception as a formal discipline in the late nineteenth century. In the United States, culture history was derived from the influential culture area studies of anthropologist Alfred Kroeber and others, and was a largely descriptive, inductive, pattern-searching approach, based on supposedly diagnostic artifacts (pottery types, projectile points, etc.) restricted in their time-space distributions to particular cultures thought to be analogous to those studied by ethnographers. Autochthonous development or culture contact was invoked to explain pattern changes in a conceptual framework in which induction constituted the only form of explanation. With the recognition that these archaeological cultures were constructs imposed on data by archaeologists, rather than demonstrably present in the past, and that limitations to an understanding of culture process were not inherent in the nature of archaeological data (as had often been claimed), but were instead due to flawed research designs and methodological naiveté, archaeologists began to look for ways to make the discipline more “science-like” and to strengthen our explanations of past behavior. This effort was largely confined to the Anglophone research traditions and was spear-headed by Lewis Binford (e.g., 1965) and Kent Flannery (e.g., 1973) in the United States and by David Clarke (e.g., 1968) in the United Kingdom. Binford is usually credited with the contention that, at least in theory, the entire cultural system was preserved in the archaeological record if only we are ingenious enough to decode

it. This in turn expanded the realm of archaeological enquiry enormously and generated much enthusiasm, particularly among younger scholars anxious to break with the culture history approach. It was in this context that hypothesis testing first arose.

Broadly defined, most hypotheses are conditional statements of relationship between two or more variables that have empirical referents. Statistical hypotheses come in mutually exclusive contrasting pairs referred to as the null (H_0) and alternative (H_1) hypotheses. The null hypothesis is typically the hypothesis of no relationship between/among the variables of interest and is constructed to be rejected. The alternative hypothesis predicates that a relationship does in fact exist between those variables. We are usually interested in demonstrating the existence of that relationship, *by seeking to reject H_0* with a specified probability of rejecting it when H_0 is true. There are two ways a correct decision can be made and two ways in which errors can occur. If H_0 is true for the population from which the sample is derived and H_0 is not rejected on the basis of an analysis of that sample, then a correct decision has been made. If H_0 is false for the population and is in fact rejected on the basis of the evaluation of the sample, then, again, a correct decision has been made. If, on the other hand, H_0 is really true for the population and is in fact rejected based on an analysis of a sample, then an error is made. And, if H_0 is false for the population and is not rejected on the basis of an evaluation of the sample, then an error of another kind is made. These two kinds of errors are called Type I and Type II errors. A Type I error occurs when H_0 is true but is rejected; a Type II error occurs when H_0 is false but is not rejected. The probability of Type I error is specified beforehand by the researcher and is called the level of significance (α , usually) of the statistical test. When the null and alternative hypotheses are mutually exclusive and exhaustive, to reject H_0 logically implies or entails acceptance of H_1 .

In archaeology, hypotheses are not evaluated directly but are instead evaluated in terms of their empirical referents, or test implications (i.e.,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0314

what we would expect to find “in the ground” if H_1 is supported empirically). In most statistical applications that involve hypothesis testing, archaeological data are considered to be samples drawn from theoretical populations whose characteristics are typically unknown. Although often ignored in practice, this fact limits the utility of hypothesis testing approaches based on parametric statistics (i.e., those that make assumptions about the defining properties of the population distribution from which the sample is drawn).

The main features of a research protocol that could be argued to characterize much quantified archaeological research regardless of the scale or nature of any particular research problem are given in Figure 1a. Sometimes called a “confirmatory mode of analysis” (CDA), it assumes that the generation of hypotheses and their evaluation in probabilistic terms is foundational in the conduct of all scientific inquiry. While clearly not the only analytical format, it is well represented in the work of contemporary professionals and it operates independently of any particular theoretical orientation.

Hypothesis testing in archaeology usually consists of seven steps that specify how one goes from (1) a general proposition of anthropological interest, to (2) an hypothesis that is meaningful in behavioral terms, to (3) propositions amenable to statistical analysis with empirical data, to (4) a procedure that defines those data, how they are to be acquired and manipulated, and in which decision-making criteria are made explicit, to (5) data collection, followed by (6) a statistical test, and (7) a reassessment of the behavioral implications of that test.

Armed with “background knowledge,” hypothesis testing begins with questions of interest to the investigator and is likely to be relevant to more tightly focused research objectives (Figure 1a, boxes 1, 2). At this stage, the investigator evaluates plausible solutions in an informal way, usually within the confines of habitual frames of reference. Many false starts are made. This exercise sometimes culminates in the development of a behavioral hypothesis (Figure 1a, box 3). A behavioral hypothesis can be viewed as a trial formulation derived from the complex factors just noted (i.e., general knowledge, background research, insight, intuition) that the investigator believes likely to express a significant

relationship between two or more variables. An explicit research design is then formulated. It tells us how to define the behavioral hypothesis empirically, what data are required to evaluate its credibility, and, often, the statistical requirements for making that evaluation (Figure 1a, box 4). The variables incorporated in a behavioral hypothesis must have phenomenological referents (test implications) (Figure 1a, box 5). In other words, they must be observable in, or recoverable from, the archaeological record and they must bear a logical relationship to the hypothesis. If they do not, there is no mechanism through which the plausibility of the hypothesis can be assessed.

At this juncture an appropriate statistical model is selected (Figure 1a, box 6). In standard CDA, the statistical model comprises the set of assumptions about the underlying properties of the population from which the sample is drawn. The relationship between the common probability distributions and the level of scaling characteristic of measurement (i.e., nominal, ordinal, interval, ratio) should be taken into account because these factors ultimately influence the choice of a test statistic. Many multivariate methods (e.g., multiple regression, analysis of variance) assume a univariate or multivariate normal distribution, equality of variance, and interval or ratio scaling. *Up to this point, no data have actually been collected* (Figure 1a, box 7). When data are acquired that meet the above constraints, they are analyzed (Figure 1a, box 8)—hopefully in accord with those constraints—and the statistical hypothesis is evaluated (Figure 1a, box 9). At this point the investigator might discover data insufficiencies, in which case, s/he returns to data acquisition (Figure 1a, box 7) and the process is repeated. If the data are determined to be adequate, a test is conducted, and the null hypothesis (H_0) is either rejected or not rejected based on the probability of Type I error specified beforehand. The result is then integrated into the broader research question from which the hypothesis is derived (Figure 1a, boxes 10, 11). Confirmatory data analysis is widely used in the physical sciences where population characteristics are known and tightly controlled experimental research protocols are the norm. So far as archaeology is concerned, a drawback to CDA is that archaeological data seldom exhibit a normal distribution or equality of variance.

Figure 1a Hypothesis testing in a confirmatory mode. Flowchart identifies 11 stages in a generalized procedure for evaluation of research propositions.
Source: Modified from Clark 1982, 233, published by Academic Press.

Figure 1b Flowchart incorporating an EDA pattern search in CDA mode for hypothesis testing.

Because archaeological data are often incomplete and do not meet the above constraints, a strong case can be made for adoption of nonparametric statistics. Nonparametric statistics are not based on parameterized families of probability distributions. Unlike parametric statistics, they make no (or few) assumptions about the probability distributions of the variables being assessed. To overstate the case somewhat for comparative purposes, nonparametric tests produce conclusions of the form: “Almost regardless of the shape of the underlying population distribution, we can conclude that . . .” In archaeological contexts “the shape of the underlying population distribution” is practically always unknown (in fact, unknowable). Like their

parametric counterparts, nonparametric statistics include both inferential and descriptive methods. Although hypothesis testing is emphasized here, nonparametric methods are also appropriate for a wide range of descriptive statistics including point estimation, measures of correlation, establishing confidence intervals, and multiple comparisons of rank-order data. Ranked data are common in many archaeological applications. The term refers to the ordinal level of scaling required for valid application. Examples include the Kolmogorov–Smirnov k -sample test, the Mann–Whitney U test, and Kruskal–Wallis one-way ANOVA. Some nonparametric statistics can be used when only nominal (classificatory)

scaling is present (e.g., the binomial test, Fisher exact probability test, k -sample χ^2 test).

Two other families of statistics, sometimes used in conjunction with one another, are directly relevant to hypothesis testing. They are exploratory data analysis (EDA) and a particular kind of simulation called agent-based modeling (ABM). Exploratory data analysis first developed in the late 1970s in response to dissatisfaction with the rigid numerical summaries that structure CDA. An empirical approach founded on the notion that as much as possible should be learned about structure in data *before* they are used to evaluate hypotheses, EDA complements, rather than replaces, hypothesis testing. Its most fundamental tenet is that all data are comprised of two components: the “smooth” and the “rough.” The smooth is the underlying simplified structure of a set of observations—the general shape of a distribution summarized in parametric statistics by the standard measures of location and spread (e.g., means, standard deviations). The rough consists of the residuals—what is left behind after the smooth has been extracted. What distinguishes EDA from CDA is a willingness to explore alternative models of relationship by the successive extraction of the smooth until nothing but unpatterned residuals remain. In a complete EDA scenario, analysis proceeds from the examination of single variables, to the bivariate case, and finally to multivariate analysis. The rationale behind this incremental approach is to understand as much as possible of the structure of each variable as an entity, to understand pairs of variables as relationships, and to understand groups of variables as models. Each step in the process is accompanied by a set of basic concepts and techniques that mirror their parametric counterparts (but *sans* the assumptions) and that emphasize visual displays of shape, location, and spread (the univariate case), strength and direction (the bivariate case), and residuals (the multivariate case).

It is interesting to note that, although EDA tends to suggest rather than confirm hypotheses, it is not incompatible with a confirmatory mode of analysis. One form such a “hybrid” research design might take is shown schematically in Figure 1b. The diagram is a partial expansion and reordering of some of the elements in Figure 1a. It differs from Figure 1a in three respects. First, data

are defined by a statistical hypothesis in a confirmatory mode of analysis. In EDA, data are defined directly from the behavioral hypothesis. Second, although the complete EDA scenario calls for a progression from univariate to multivariate analysis, in many archaeological applications only part of the procedure will be fully utilized (Figure 1b, boxes 7–9). Third, the behavioral hypothesis is restated in EDA terms (Figure 1b, box 10), evaluated directly (Figure 1b, box 11), and the decision to accept or reject it is integrated into the broader research questions that frame the hypothesis (Figure 1b, box 12).

While there is consensus that EDA can play an important role in hypothesis formulation, there is some divergence of opinion as to what role EDA should play in hypothesis testing. Some have suggested that EDA forfeits the right to evaluate the statistical significance of research conclusions, since they are not based on formal, *a priori* statistical hypotheses (i.e., EDA hypotheses are derived directly from sample data, and therefore to test for significance using those data would be meaningless) (Hartwig and Dearing 1979). Others claim that because EDA hypotheses can sometimes “map onto” nonparametric probability distributions, significance testing remains a possibility. Despite its research potential, archaeologists were slow to adopt EDA. It only became common in the literature in the 1990s, possibly because it is described in terms of an unfamiliar vocabulary likely to have been a considerable obstacle to graduate students exposed only to finite mathematics and nonparametric methods.

The second approach, agent-based modeling (ABM), has gained traction since 2007 because of the realization that *all* societies are complex adaptive systems (CAS) regardless of size or organizational structure (i.e., that “complexity” is not confined to “states”), are dynamic in space and time, and are fluid in membership and in how information is transmitted and processed, and that it is these multilevel, multiscale interactions that allow societies to adjust to changing internal (biosocial) and external (biophysical) conditions. Societies are seen as emergent phenomena created and transformed by the actions of individuals who “ascribe to a common body of knowledge but who make decisions contingent on the practices of other actors and the structure of social

interactions, as well as the biophysical characteristics of their environment” (Barton 2014, 309). CAS advocates maintain that the descriptive and inferential statistics that dominate quantitative archaeology today are ill-suited to deal with these complex, multilevel interactions which can only be “captured” by simulations. Although archaeological applications go back to the 1970s, they are very rare and have not before now been situated in a relatively coherent conceptual framework.

ABM can best be viewed as an experimental laboratory in which to explore nonlinear causality in complex systems and generate test implications that can be evaluated empirically against the archaeological record. It works “from the bottom up” by creating multiple, discrete computational entities (agents) that behave according to specific interaction rules (algorithms) that define how those agents process information, make decisions, and take action based on those decisions. Once the agents are specified and the rules defined, they interact in a virtual environment without further intervention by the researcher, offering a useful protocol for combining anthropological knowledge of complex adaptive systems to explore patterns that otherwise would not be apparent (Barton 2014, 311).

Like EDA, ABM can be used “by itself” in either a descriptive or inferential (hypothesis testing) mode, and can also be integrated into larger and more complex research designs. Challenges to application include the fact that many questions of archaeological interest lie “just out of reach,” with test implications that require considerable ingenuity to operationalize. ABM also abounds in unfamiliar concepts and terms embedded in the CAS literature (e.g., Cowan, Pines, and Meltzer 1994) and requires a fairly steep learning curve. Perhaps its greatest potential for hypothesis testing lies in using it to model systematic, controlled, digital environments for human socioecological dynamics.

As noted, archaeology “came late” to quantitative methods and, in consequence, hypothesis testing was not an historical part of its research protocols. A comparison of the incidence of statistical applications in articles published in *American Antiquity* over the 1935–75 interval showed mostly enumeration (8–12 articles/5 years), with minimal use of basic statistics (5–12

articles) and almost no advanced methods (0–7 articles) (Clark and Stafford 1982). After 1975, statistical usage shows a sharp upswing that continues to the present, largely as a consequence of efforts to introduce a deductive component manifest in hypotheses and their test implications into its research protocols (e.g., Watson, LeBlanc, and Redman 1971). A single recent issue of *American Antiquity* (Vol. 81, No. 2, April 2016) contains applications of Simpson’s *C* (and its reciprocal), Manning’s *Q*, the correlation coefficient *C* (the nonparametric equivalent of Pearson’s *r*), discriminant functions, EDA, principal component analysis, bivariate plots, and Bayesian models, along with LiDAR, GIS, ArcGIS, GPR, NAA, and other geophysical methods, generally within a broadly defined behavioral ecology conceptual framework.

Inferential Statistics

ENRICO R. CREMA

University of Cambridge, UK

Statistical inference is a scientific process whereby properties of a population are deduced from an observed sample. Here, the term population refers to a definable collection of materials or events, each associated with one or more measurable properties characterized by some variability (e.g., a certain size range might have higher or lower frequencies than others) that can be mathematically modeled as *probability distributions* defined by one or more *parameters*. The primary objective of statistical inference is thus to determine, by analyzing observed samples, which statistical model best describes the observed distribution of variables, and at the same time estimate its parameter values. Thus, statistical inference is in contrast with descriptive statistics (see DESCRIPTIVE STATISTICS), which instead looks at the properties of the observed samples alone.

The core element of statistical inference is the selection of a statistical model: an abstract conceptualization of real-world variability capable of capturing a wide range of phenomena with few assumptions. Consider, for example, a group of individuals engaging in the production of some artifacts targeting an ideal form. Most likely, many small factors, such as different skill-sets, different perceptions of the ideal form, or the idiosyncrasies of the material, will generate variations in the size and shape of the artifact. With a sufficiently large sample size, these variations often follow a bell-curve, where the majority concentrates around a central value from which the data spreads symmetrically. This distribution can be described using the *normal distribution*, a statistical model that can portray key properties of this variation with just two parameters: the *mean* (which depicts the central tendency) and the *variance* (which depicts the spread of the variation). Statistical models enable us to quantify, for a given model and a defined parameter,

the probability of observing a particular value (in the case of discrete data) or range of values (in the case of continuous data). So for example, the probability of observing a projectile point with a length between 12 and 14 cm is 0.136 for a normal distribution with a mean of 10 and a variance of 4, whilst observing a length over 16 cm would have a probability of only 0.001. The distribution defining these probabilities is called a *probability distribution*. Different parameters would indicate different probabilities of observing a given range. Thus, observing a projectile point with a length between 12 and 14 cm would have a probability of 0.021 if the mean was 8, whilst with a mean = 13 this would increase to 0.383. We can extend this concept and compute, for a set of observations $x_1, x_2, \dots, x_n$ and a parameter value θ , the probability of observing all the sample data values. This is known as the *likelihood function*, and plays a pivotal role in statistical inference, as it enables a direct link between data and model.

Considering these foundational concepts, statistical inference is generally performed using three broad paradigms: *frequentist inference*, *likelihood-based inference*, and *Bayesian inference*.

Frequentist inference is perhaps the most widely adopted paradigm within and outside archaeology. It generally consists of a two-step process. First a *null hypothesis*, a statistical model with a given parameter, is defined. Then, given sample data, we estimate the probability of finding the observed or more extreme pattern *if the null hypothesis is true*. It follows that if this probability, known as the *p-value*, is low (generally below an arbitrary threshold of 0.05), the null hypothesis is rejected. This single hypothesis testing approach is known as *Fisher's method*, and it is slightly different from *Neyman-Pearson's method*, which instead consists of choosing between a null and an alternative hypothesis. In this framework, one first defines a priori two values representing our probabilities for committing inferential errors (α , the probability of falsely rejecting a true null hypothesis; and β , the probability of failing to reject a false null hypothesis), and then using these as thresholds for defining ranges of

values for the acceptance and rejection of the null hypothesis. One of the most common problems of the frequentist inference is the misuse and misinterpretation of the p -value. This is sometimes erroneously interpreted as the probability of the null hypothesis being true, or that its value is inversely correlated to the strength of the phenomena. The p -value is instead the outcome of many factors, from the choice of the null hypothesis to the size of the sample and the strength of the phenomenon of interest (known as *effect size*). In many situations a small sample size might fail to correctly reject a false null hypothesis, whilst a large sample size might lead to an incorrect rejection of a true hypothesis. An appropriate balance between these factors can be evaluated by means of a *power analysis*, a technique that can advise the suitable sample size required for avoiding false positives and negatives. Its application in archaeology is, however, rare (but see Wolverton, Dombrosky, and Lyman 2016), partly due to the limited possibilities for designing appropriate sampling strategies in many situations.

Likelihood-based inference is centered on the idea that likelihoods can be used to compare models. From an epistemological point of view, the key difference of this approach compared with the classical frequentist one is that it entails an explicitly comparative perspective, where the ratio of the likelihood of one hypothesis over the other measures the strength of evidence for the former over the latter. One potential problem with comparing models based simply on their likelihood is that models with more parameters often tend to have higher likelihood. This is due to the problem of “over-fitting,” a process by which a statistical model describes the noise instead of the deeper structure of the observed data, weakening its predictive power and countering the law of parsimony. A more sophisticated tool, referred to as *information criteria*, overcomes this problem by penalizing models with higher number of parameters, providing a valuable tool for comparing multiple hypotheses at the same time (see Silva et al. 2015 for an archaeological example).

Bayesian inference (see BAYESIAN STATISTICS) offers a substantially different epistemological stance rooted in the notion that knowledge of model parameters can be updated by combining

prior beliefs (described as probability distributions) with newly observed data (which relationship to the model is defined through the likelihood function). This is a rather intuitive and commonly used inferential framework. For example, in provenance analysis one might choose to ignore source sites located at great distances from where an artifact has been recovered. This constitutes an informal use of a prior belief (in this case the assumed unlikelihood of long-distance sourcing); Bayesian statistics provides the mathematical tools for formalizing this kind of inferential process. In archaeology, its widest application is within chronometric analysis, where the combination of multiple lines of evidence (such as stratigraphic relationships) can often dramatically improve radiocarbon dating (e.g., Buck, Litton, and Smith 1992).

Bayesian inference is occasionally criticized for the inherently subjective way in which priors are defined. This, however, wrongly implies that other paradigms are not affected by subjective accounts, while in fact in many cases these are hidden in the choice of methods and data. The need to provide quantitative measures of assumptions should perhaps be viewed instead as a strength of this statistical paradigm, as it offers an increased transparency in determining the role played by subjective beliefs in the inferential process. Despite its suitability for tackling many archaeological problems, Bayesian analysis is still not as widely adopted as other paradigms. This is partly due to its mathematical intractability, which often requires the use of computer simulations. Recently this weakness has been turned into a strength, with novel simulation-based approaches such as approximate Bayesian computation, which offers a Bayesian inferential framework without the need for a likelihood function and a statistical model. This greatly expands the potential range of applications of statistical analyses, which can benefit from the flexibility of computational modeling and the mathematical rigor of statistical inference (see, e.g., Crema et al. 2014 for an archaeological example).

Linear Models

EFTHYMIA NIKITA

Science and Technology in Archaeology Research
Center, Nicosia, Cyprus

In statistics a *linear model* is a relationship between a dependent (response) variable, y , and one or more independent variables (predictors or explanatory variables), $x_1, x_2, \dots, x_p$, of the general form:

$$y = b_0 + b_1x_1 + b_2x_2 + \dots + b_px_p$$

where $b_0, b_1, \dots, b_p$ are the model *adjustable parameters*.

Note that *interactions*, for example, terms of the product of two or more predictors, may also be included in the model. When there is a single independent variable, the relationship between x and y may be simple linear ($y = a + bx$), quadratic ($y = a + bx + cx^2$), cubic ($y = a + bx + cx^2 + dx^3$), or, in general, a polynomial of degree p ($y = b_0 + b_1x + b_2x^2 + \dots + b_px^p$). The adjustable parameters are initially unknown and they are determined through a fitting procedure called *regression*. Depending on the nature of the response variable and the predictors, as well as the regression procedure, there are several types of linear models, which are briefly presented below. Note that conventional statistical tests such as ANOVA, MANOVA and even t -tests may also be conducted via linear models, but this application will not be discussed here.

Types of linear models

In *ordinary least squares* (OLS) fitting (model I regression), the regression model corresponds to the minimum of the sum of the squared residuals, where a *residual*, d_{ix} , is the difference between the experimental and the calculated from the model y_i value at a certain x_i or ($x_{1i}, x_{2i}, \dots, x_{pi}$) value.

Thus, the ordinary least squares criterion is:

$$d_{1x}^2 + d_{2x}^2 + \dots + d_{Nx}^2 = \min$$

with N being the number of experimental points.

The underlying assumption of this process is that measurement errors concern exclusively variable y . When both independent and dependent variables are subject to experimental errors, the OLS fitting is no more reliable. In this case, the regression procedure (model II regression) should minimize the errors in both variables. There are several ways to do this. In reduced major axis (RMA) fitting, also known as standard major axis regression, the sum that is minimized is:

$$d_{1y}d_{1x} + d_{2y}d_{2x} + \dots + d_{Ny}d_{Nx} = \min$$

where d_{iy} is the difference between the experimental and the calculated from the model x_i value at a certain y_i value.

Analysis of covariance (ANCOVA) is an extension of the previous OLS models, which, additionally to continuous predictors, includes nominal and/or ordinal independent variables. Thus, ANCOVA generates predictions at the various levels of a categorical variable, while controlling for the effects of one or more continuous variables. From a statistical point of view, ANCOVA may be considered a combination of regression analysis and ANOVA.

Generalized linear models (GLMs) extend ordinary linear regression to cases where the dependent variable comes from any exponential family distribution (i.e., normal, binomial, Poisson, etc.) and is recorded as a function of continuous and/or categorical variables. GLMs require that there is no correlation between the values of the dependent variable. If this condition is not met, *generalized estimating equations* (GEEs) should be used instead. Therefore, GEEs are a version of GLMs, applicable when there is more than one measurement per individual. For example, this is the case when bilateral asymmetry is examined.

Logistic regression is a special case of GLM, where the response variable is binary, while the

predictors can be discrete and/or continuous. However, in most cases, discrete predictors are treated as continuous variables. Note that the logistic regression model, as well as GLM with a binary response, does not predict the response variable; rather, they estimate the probability of this variable belonging to each one of its categories.

Linear models have been used to address diverse archaeological questions, which are related to prediction and/or correlation. In particular, linear models have been employed to: (1) predict the average value of a certain property for a “new” case for which only values of the predictors are measured/observed; and (2) assess the contribution of each predictor to the response variable, which, in fact, means the examination of the partial correlation between each predictor and the dependent variable, while controlling for the effect of the other predictors, that is, by excluding the effect of the other predictors. The latter case may also include the examination of *interaction effects*, that is, whether a predictor has a different effect on the response variable depending on the values of another predictor. Both these tasks may be best handled if, based on the total number of predictors, the optimum linear model is selected, that is, the simplest linear model that adequately fits the data. When a response variable is recorded as a function of several explanatory variables, the optimum linear model is usually determined as follows. Starting from the *saturated* model or from any model that includes all the predictors and several of their interactions, the non-significant predictors and interactions are removed one by one. This procedure ends when only significant predictors are left in the model. Alternatively, the statistically optimum model may be selected from the smallest standard error of estimate or the smallest Akaike information criterion. Both these criteria are measures of the relative quality of a model, that is, they assess the quality of a model relative to other models. However, at this point a methodological issue should be highlighted. When conducting tests of main effects and interactions, the *p*-values of the model coefficients are used in order to assess whether their contribution to the response variable is significant. This is a case of multiple tests performed on the same data, and a common statistical practice is to adjust the *p*-values, say

using the Holm-Bonferroni method. However, this adjustment is rarely applied in relevant studies, and this omission may yield misleading results.

Applications in archaeology

The applications of linear models in archaeology are extremely broad, covering diverse topics. For this reason, only indicative examples are given below. Most of these examples have been drawn from osteoarchaeology, although brief mention is made of other subject areas.

One of the first applications of linear models is for prediction. Simple linear models have been adopted in a number of worldwide studies to predict stature from long bone length, or body mass from femoral head diameter (see, for example, Ruff et al. 2012). Such approaches are based on the correlation that exists between the size of individual skeletal elements and overall body size. Most studies have adopted OLS models, but RMA has been assumed to provide more accurate results for extended size ranges (Ruff et al. 2012). Furthermore, polynomial regression equations have been used for the prediction of age-at-death based on tooth crown heights (Mays and Pett 2014). In addition to producing regression equations for prediction, Mays and Pett (2014) used ANCOVA in order to compare the slope of the regression lines for deciduous first and second molars and found these to be significantly different, supporting a different rate of dental wear between these teeth.

Regarding applications involving non-continuous variables, logistic regression has been employed to predict the sex of individuals based on combinations of morphological skeletal markers. In such cases the dependent variable (sex) is a binary dichotomy (male–female), whereas the predictors are characteristics recorded in an ordinal scale with the ranks of this scale representing different degrees of masculinity and femininity (Walker 2008). Such approaches provide not only a sex assessment but also the probabilities of the individual being male or female.

In addition to predictions, the examination of correlations through linear models constitutes

a promising research direction in archaeology. Such an approach is particularly useful when exploring multifactorial phenomena as it allows the simultaneous examination of multiple predictors by testing the effect of each one while controlling for the effects of the remaining variables. For instance, logistic regression has been used for the study of the expression (presence-absence) of osteoarthritis, using as predictors the age, sex, and community residence of the individuals under study (e.g., Baker and Pearson 2006). In different contexts, logistic regression has been used among others to identify the variables that allow the effective differentiation of taphonomic agents (trampling marks vs. butchery cut marks) on zooarchaeological remains (Domínguez-Rodrigo et al. 2009), or the determination of iron-making practices (bloomery vs. finery) in medieval monuments using the percentage concentration of oxides as predictors (Disser et al. 2014).

As an extension of logistic regression, GLMs and GEEs have been adopted in osteoarchaeology for the study of the variables that affect enthesal changes. Enteses are the sites of muscular attachment on the bones, and morphological changes observed on these sites have been interpreted as activity markers. However, factors such as sex, age, and body size also appear to be highly influential in the expression of enthesal changes. GLMs and GEEs offer an effective means of exploring the simultaneous impact of these variables and their interactions on enthesal changes (Nikita 2014). Similarly, these methods have been adopted in the study of paleopathological conditions with a multifactorial etiology, such as dental diseases (Gagnon and Wiesen 2013). As was the case for logistic regression, GLMs and GEEs use disease expression as a response variable, and sex, age, sample chronology, and other potentially important variables as predictors. An important advantage of GLMs and GEEs compared with logistic regression is that the response variable may be binary, ordinal, continuous, or even counts. An example concerning the latter case is provided by Browne and Wilson (2013), who used GLMs to examine the most effective model of hominin raw material procurement, with an emphasis on the impact of map resolution and path choice (straight line, least cost). In this application, different GLMs were tested,

with the number of stone tool pieces used as the dependent variable, and ten variables expressing raw material properties and environmental data used as predictors.

Lithics Data Quantification

W. JAMES STEMPEL

Keene State College, USA

Lithics data quantification in archaeology includes three main approaches that focus on instrumental analysis and mathematical description and characterization of stone tool form and function. Specifically, archaeologists studying lithic technology of the past increasingly rely on methods of quantification that focus on geometric morphometrics, microwear analysis, and residue analysis.

Lithic form: geometric morphometrics (GM)

At its most basic level, determining stone tool sizes and shapes is based on measurement on ratio or two-dimensional (2D) scales (e.g., length, width, thickness). More complex mathematical documentation of stone tool shape involves a number of different geometric morphometrics (GM) techniques to produce two-dimensional (2D) and three-dimensional (3D) models that are virtual true-to-scale copies of the original tools. Borrowing from biometric studies of organism form, archaeologists have quantitatively documented the shapes of stone tools (Shott 2014) using landmarks on the original tools for geometric modeling. Methods currently being employed by archaeologists to produce these virtual models include photogrammetry, various forms of laser, structured-light, and X-ray scanning, in addition to tools like contact digitizers and those that incorporate traditional linear measurement data acquired through manual acquisition of landmarks (Shott 2014).

Photogrammetry, which relies on the calculation of stone tool measurements based on series of digital images, involves point-to-point matching of landmarks on the overlapping photographs/images taken from different angles in order to replicate the tool with a point cloud and

triangular mesh frame. The number of images and the number, locations, and proper matching of points from these multiple images will affect the quality and accuracy of the virtual reconstruction (Sumner and Riddle 2008). Other approaches to morphometrics involve 3D scanning of lithic artifacts using a variety of technologies, including 3D laser scanning, structured-light scanning, and X-ray measurement systems, that are coupled with modeling software. The equipment employed to scan the lithics includes a wide range of options, ranging from relatively inexpensive digital cameras and desktop laser scanners to much more costly laser scanning systems and micro-computed tomography (CT) scanners (Shott 2014). Laser scanners sweep the surface of the stone tool using a laser that documents thousands of surface points that are connected using a triangular mesh, somewhat like photogrammetry. Unlike photogrammetry, which requires the human selection and placement of necessary points on an imaged stone tool surface, laser or structured-light approaches (Figure 1) do all of this automatically once the level of scan definition is set by the operator. Volumetric scanners, like micro-CT, rely on X-ray transmission to mathematically document the material based on cross-sections to reproduce the stone tools accurately in three dimensions (Abel et al. 2011; Grosman, Smikt, and Smilansky 2008).

Examples of the application of these methods include the virtual reproduction of Acheulian hand axes and Levallois core and flake tools, typological classifications, and the documentation of technological details on chipped stone tools (e.g., cortex coverage, flake directionality, retouch and refit studies, and raw material texture) (Abel et al. 2011; Grosman et al. 2008; Shott 2014; Sumner and Riddle 2008). Virtual modeling may be used to produce 3D replicas of lithic artifacts from epoxy resins/plastics. Consequently, virtual documentation and quantification of stone tools have significant curatorial and exhibition benefits, as well archaeological data-sharing applications (Abel et al. 2011; Shott 2014; Sumner and Riddle 2008).

Lithic function: microwear analysis

Microwear analysis relies on the observation and documentation of edge or surface alteration of stone tools resulting from use. Stone tools are examined using various types of microscopes, from low-power ($<100\times$) stereomicroscopes to high-power ($200\text{--}500\times$) metallurgical and ($>500\text{--}10,000\times$) scanning electron microscopes (SEM). Lighting of tool surfaces, typically angled or direct/reflected, permits observation of different types of wear features at different magnifications. Identification of tool use is based on the interpretation of the combination of wear features (e.g., edge microchipping, edge rounding, striations, and micropolish/abrasion) observed by the microwear analyst and the subsequent assignment of most likely function of the tool in terms of tool motion (e.g., cutting, drilling, scraping) and the contact material based on either hardness (e.g., soft, medium, hard) or more specific type (e.g., bone, hide, wood) (Stemp, Watson, and Evans 2016).

Quantification of microwear does not rely on the visual interpretation of use-wear features; it uses mathematical data derived from the stone tools' edges and surfaces to determine function. Much of the method and theory for edge and surface quantification employed by archaeologists is borrowed from the engineering fields of metrology and tribology (Evans and Macdonald 2011; Stemp et al. 2016). Early attempts at quantification of microwear included techniques using measurement of edge fractures and loading principles, as well as white light interferometry, profilometry, and different forms of digital image analysis, among others (Stemp et al. 2016). Technologies to

quantify lithic surfaces on micro- and nano-scales include atomic force microscopy (AFM), laser profilometry, interferometry, laser scanning confocal microscopy (LSCM), white light confocal microscopy (WLCM), and focus variation microscopy (FVM). These measurement systems are coupled with various software packages for the calculation of surface texture/roughness using algorithms, such as average roughness (S_a), root mean square roughness (S_q), relative area (Srel), and area-scale fractal complexity (Asfc) (Evans and Macdonald 2011; Stemp et al. 2016). In addition to the mathematical documentation of surface texture/roughness, these systems can generate 2D and 3D images of the tool surfaces, thus providing a visual complement to the quantified surface data (Figure 1b).

Most of this work is in its experimental stages, focusing on increasing understanding of wear formation processes on stone tools, the effects of post-deposition on lithic microwear, discrimination of wear resulting from contact with different worked materials, wear development and use-duration, and wear on various raw material types (e.g., flint, chert, obsidian, quartzite). However, there are applications to lithic artifacts, including Upper Paleolithic flint tools from England, Neolithic flint tribulum blades, an obsidian bracelet fragment from Neolithic Turkey, and Mousterian flint tools from Russia, to name a few (Evans and Macdonald 2011; Stemp et al. 2016).

Lithic function: residue analysis

Traditional residue analysis is based on microscopic observation and morphological

identification of the remains of animals (e.g., blood, fats, lipids, collagen, keratin), plants (e.g., starch grains, phytoliths, raphides, pollen, cellulose), or other substances (e.g., ochre, cinnabar, metals) adhering to lithic artifact surfaces. Residues may be observed and analyzed while still adhering to the stone tools or they may be extracted for later observation and analysis. As with microwear analysis, microscopes of various magnifications, lighting arrangements (i.e., reflected, transmitted), and polarizers are used for this purpose, including low-power stereomicroscopes, high-power metallurgical microscopes, and scanning electron microscopes (Monnier et al. 2013; Rots et al. 2016). Extracted residues that are degraded, fragmented, or otherwise amorphous can be identified using stains, such as Methylene Blue for cellulose or Orange G for collagen and keratin. Identification of residues can also be accomplished by using biochemical reagents, most notably for immunological reactions to suspected blood proteins, and DNA analysis (Rots et al. 2016; Stemp et al. 2016).

Quantification of residues is primarily based on the measurement of molecular compounds, minerals, and trace elements in the residues that can be used to objectively identify the substances on the surfaces of stone tools by matching them to the compositional data of known materials. Various techniques are employed for these analyses of both organic and inorganic residues, including gas chromatography mass spectrometry (GC-MS), liquid chromatography mass spectrometry (LC-MS), Fourier transform infrared spectroscopy/microscopy (FTIRM), Raman spectroscopy/microscopy, X-ray diffraction (XRD) analysis, and scanning electron microscopy with energy-dispersive X-ray spectroscopy (SEM-EDX). Each of these techniques measures residue composition differently, but identification is based on the production of a unique chemical signature (i.e., size and position of peaks of the substance sampled when graphed) (Figure 1c). These residue analysis techniques can be combined with optical microscopy to provide both visual and compositional data (Monnier et al. 2013; Prinsloo, Wadley, and Lombard 2014).

Certain residues may become adsorbed into the tools' stone matrix during the process of wear and can be detected based on the analysis of the elemental composition of lithic surfaces

themselves using techniques such as ion beam analysis (IBA), laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), proton-induced X-ray emission spectroscopy (PIXE), and Rutherford backscattering (RBS) (Evans and Donahue 2005). This information is not only employed to determine tool function, it has also been incorporated into the debate about wear formation processes on chipped stone tools. Two main concerns when attempting to identify residues using any of the visual or quantitative techniques presented above are residue degradation and environmental/depositional or human contamination of the samples (Monnier et al. 2013; Prinsloo et al. 2014). Some archaeological and experimental examples of quantification of residues include the identification of bitumen on lithic artifacts from Syria and animal residues on tools used in hunting and butchery of blue wildebeest, among others (Monnier et al. 2013; Prinsloo et al. 2014).

Increasingly, various morphometric, microwear, and residue analysis methods based on quantification of data derived from lithics are being used by archaeologists around the world. Many of these methods are in various stages of development, with some still in early experimental phases that require further testing. Overall, results using these methods for quantification of lithic form and function are promising. Increasingly, quantitative data derived from these methods of stone tool analysis are being combined with more traditional approaches, such as photography/illustration and optical microscopy (Stemp et al. 2016), to provide more detailed information about how lithic artifacts were made and used in the past by humans and their hominin ancestors.

Mathematics

IGOR BOGDANOVIC and JUAN A. BARCELÓ

Universitat Autònoma de Barcelona, Spain

Mathematics underlies a number of scientific methods used in archaeology today and exercises a great influence on all survey, excavation, and recording procedures. The ambiguities and imprecisions of verbal description and narratives which characterize traditional archaeology are being substituted by mathematical language and formalized datasets preconceived for use in automated computer-based analytical processes (see COMPUTER APPLICATIONS IN ARCHAEOLOGY). These changes follow the general shift in the way that knowledge is built, shared, and communicated by the scientific community, and how it is acquired by society. Computer technology allows processing a great amount of data and rapidly performing complex mathematical operations, reinforcing the use of a wider empirical base in archaeological knowledge and enhancing an overall use of mathematics in archaeology.

Mathematics not only is a tool that can serve in archaeological research but also can be used to represent the structure of an archaeological *problem*, that is, questions raised regarding archaeological material and the past in general. An enquiry into past social realities can be expressed as a relation between causes and consequences. For example, *what differences in actions* (production, use, distribution, and so on) *are the causes of the observed variations* (size, form, composition, texture, localization, etc.)—and vice versa. Whenever we express an idea through an order relation of its components, we can express it mathematically. The subjective terms and concepts traditionally linked to expressing archaeological problems can therefore become explicit and well defined in formal terms through mathematics. Material evidence of past social action is distributed in

space and time as a consequence of causally related events. The most precise way to describe material evidence and its distribution in space and time is to apply artificial language to express observed and measured relations. The basic unit of artificial language is *quantity*. Certain entities possess “quantities” of something, for example, gradation and intensity. On the contrary, *qualities* are not equivalent to gradations and cannot be expressed in terms of order. They must be expressed as either “present” or “absent” (0–1). *Quantities* allow the ordering of objects or phenomena in terms of relations of order. Hence, if an archaeological problem is advanced as a mathematical structure with formalized datasets, then mathematics can be applied to solve it.

Nevertheless, the use of numbers or formal language to describe the archaeological record is still rare. The use of mathematics was an exception rather than a norm back in the 1970s (Orton 1980), and even today lacks support among most archaeologists. Yet advances in computer technology allowed the first early applications in archaeology in the 1960s (Doran and Hodson 1975). At that time, the success of quantitative archaeology was associated with computerization and algorithm improvements for cluster analysis, scaling techniques, “factor” analysis techniques, and multidimensional data analysis. The very idea of quantitative archaeology took a step forward between 1975 and 1990 as seen by the transition from a preliminary theoretical discussion to the application of quantitative methods to archaeological data, the diffusion of multidimensional data analysis, the development of new algorithms, and the possibility of using ready-made software. About the same time, new theoretical developments in archaeology influenced by “new archaeology” or “processual archaeology” emphasized scientific methods in archaeological research based on statistical tests, algebraic models, spatial analysis, system dynamics, linear programming, and the catastrophe theory. After 1990, the research based on quantification of archaeological data and the development of new methods decreased,

DOI: 10.1002/9781119188230.saseas0368

probably due to new theoretical trends in social sciences and humanities such as, for example, post-modern paradigms and the collapse of formal rationality.

Mathematics today is embedded in software applications used in archaeology such as database management (see DATABASES IN ARCHAEOLOGY), tele-detection, geographic information systems, visualization, virtual reality (see VIRTUAL REALITY MODELING), and artificial intelligence (see ARTIFICIAL INTELLIGENCE). Computing seems to be at the center of much interest in heritage studies. “New mathematics”—chaos theory, fractals, neural networks, nonlinear systems, multi-agent systems, Bayesian statistics (see BAYESIAN STATISTICS)—is being successfully tested in archaeology, confirming the fundamental role of mathematics in the description and explanation of complex archaeological systems.

The first domain where “numbers” are used in archaeology is in data acquisition and description. The properties of size, shape and form, texture or visual appearance, and finally matter and location (the position of the object in space and time) require accurate structured and formal description. This domain is fundamental for archaeological classification (see ARCHAEOLOGICAL CLASSIFICATION), that is, ordering information for subsequent measuring, counting, and comparing. From the amount and/or differences among archaeological observables, we can measure and quantify social action. Quantity of labor, efficiency of tools, and cost/benefit ratios of hunting or herding are examples. The mathematics of similarity and inductive inferences is also relevant to

archaeology. Two objects may be “implicitly” related or connected in spite of dissimilarities. Furthermore, theory and methodologies drawn from complex network models are increasingly explored as a means of understanding dynamic social relationships in the past. Another key domain where mathematics is fundamental is chronometry, or chronological modeling. The way to reconstruct a temporal ordering and its specific metrics is of the utmost relevance in archaeology because of the temporal variation in the approach to the very idea of change and evolution.

All of the cited domains converge in one of the most powerful tools for analysis and interpretation of historical processes: computer simulation. The simulated models serve to understand archaeological observables in terms of a priori relationships between observed assets and the inferred properties/abilities of people having generated them.

Measurement Theory

GUY GIBBON

University of Minnesota, USA

Science has embraced evidence-based measurement as the dominant criterion for valid knowledge about the physical and social worlds. Accordingly, the theoretical foundations of measurement are a concern of scientists and philosophers. In the process, rules and assumptions have been proposed and debated as a basis for valid measurement. Measurement theory is the justifying logic behind this rule-making process (Roberts 2009; Tal 2015). This entry reviews traditional concerns and recent trends in measurement theory.

Traditional concerns of measurement theory

For much of the twentieth century, measurement was considered the assignment of numbers to properties of material and immaterial systems with the expectation that the structure of the numbers and the systems are isomorphic. Among the problems of measurement in this view are representation, error, and scale. The problem of representation is concerned with the justification of the assignment of numbers to properties of objects. A simple example is to show that the number of items in a sample is isomorphic with the set of real numbers (1, 2, 3) in an absolute numerical scale. The problem of error is concerned with accounting for the difference between actual and observed measurements. The traditional belief was that errors in measurement could be reduced by refinements in measurement theory and instrumentation.

The problem of scale concerns the scale type appropriate to a particular measurement procedure. The most commonly used scale of measurement was and remains the nominal, ordinal, interval, and ratio scale. An example

in archaeology of a nominal scale attribute (in name only) is the presence or absence of notching on a projectile point. An ordinal scale attribute (forming a sequence with no fixed distance between measures) is a ranked measure like light or heavy grinding on the point. An interval scale attribute has an arbitrary zero point but a fixed distance between measures like calendar dates for points. A ratio scale attribute is similar but has a fixed zero point, such as length and weight measures. Determining at which scale a measurement is made was considered important, for it affects the types of numerical procedures that could be applied to the resulting data.

Throughout this period, measurement theory was embedded within positivism, a strongly empirical philosophy that assumed (among other things) that: empiricist observation is the only rational means of exhibiting the laws of the social world and human mind; universals do exist for the social world and human mind; universal truths can be established through the rational application of the scientific method; observation and measurement are the core of the scientific enterprise; and observations and theoretical terms are different realms of being, with observations matters-of-fact and theoretical terms subjective (Uebel 2011, section 3). These views led to attempts like operationalism and conventionalism to coordinate observations and theoretical terms.

Recent trends in measurement theory

Although necessarily oversimplified here, the above views had a stultifying effect on archaeology and the social sciences, for notions like social systems and their change cannot be directly observed in the same manner as a rock or a tree can. The result was the labeling of social science as “soft,” its endeavor as “speculative,” and its use of measurement problematic at best. In archaeology, measurement was largely confined to characteristics of observables like artifacts using the scales mentioned above, though advances in

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0369

technology expanded how these measurements could be made and represented.

Trends in measurement theory since the 1980s have highlighted weaknesses in traditional measurement theory. These trends redefine what observation and measurement mean, and the purpose of measurement, among other suggested redefinitions (Tal 2013; Michell 2003; Dixon-Romain and Gergen, undated). For example, because of the nature of perception and its situation within sociocultural settings, all observation, and objectivity more generally, is theory-laden; as a consequence, scientific theories are revisable and their final “proof” questionable; rather than a search for universals, interest has turned to the particularity of individual sociocultural settings; and the demonstration that the empirical tradition of measurement is at odds with the workings of the human mind has led to the investigation of what scientists actually do in practice.

The advent of model-based theories has led to the suggestion that models and simulations are in fact measurement systems themselves, even when not cast in mathematical form. These developments led in turn to the importance of coherence among the elements of these methodologies and to the problem of observational grounding, for just what is empirical and what is theoretical is in actuality blurred. Finally, social scientists have become increasingly concerned with the purpose of social science in an age of seismic changes in social life. To paraphrase Biesta (2009, 1), “should we value what we measure or measure what we value?” In archaeology, Doran (2015, v) suggests that archaeologists should be “using such access as we have to our past to guide our choice for our future as a species.”

Trends in measurement theory challenge archaeologists to be more open in their

conception of and creative use of measurement. Unleashed from the constraints of positivist views of measurement theory, archaeologists have the opportunity in the twenty-first century to greatly expand our understanding of the past and our future as human beings.

Multivariate Analysis

JOAN NEGRE

Universitat Autònoma de Barcelona, Spain

Multivariate analysis (MVA) encompasses the ensemble of statistical techniques that simultaneously try to expose the underlying meaning of datasets with several measured variables for each entity. Its principal objective in our discipline is to obtain a better description of the data under analysis by reducing it to a form that may be used to inspect its structure from an archaeological perspective.

These methods, consolidated within the general toolset of quantitative archaeology since the early 1980s, have proved their usefulness in plenty of archaeological case studies over the years. Nevertheless, the majority of those works have incessantly pointed out a structural problem: While mathematical training among archaeologists was, in the best-case scenario, superficial, historical reasoning made by statisticians who tried their hands at archaeology was usually no better. On the bright side, archaeologists seem to have reached a clear consensus on the importance of MVA in the discipline. Despite the lack of enthusiasm for these methods within current mainstream archaeology, their effectiveness in helping to understand complex datasets has given them a place in both university curricula and scientific journals.

A brief history of multivariate analysis in archaeology

The use of MVA in archaeology began in the mid-1960s, highly related to the general development of quantitative methods in social and human sciences. Despite a first attempt to introduce this general framework in archaeological research in the early 1950s by Oliver H. Myers, the first book dedicated to the matter was edited by Heizer and Cooke in 1960. The very idea

of quantitative archaeology was based at that time on the implementation of multidimensional matrices for data management and, therefore, the development of MVA, as regarded by Clarke and Gardin in their first works. This seminal scenario is only understandable within the context of computational development and its implementation for academic basic research. That was the breeding ground for the beginnings of a quantitative revolution in archaeology, which took place between the mid-1960s and the next decade. Some of the first applications of statistical techniques to archaeological datasets were developed through those years in the works of Hodson, Doran, Binford, and so many other pioneers.

The decade of the 1970s saw the consolidation of computer-aided systems that made possible the implementation of an increasing number of complex algorithms for multidimensional data calculations. Two main schools of MVA in archaeology were developed through that period around different leading researchers: One in the United Kingdom focused on multidimensional scaling methods, and the other one, established in France, was mainly working on several applications of correspondence analysis. Research efforts in this field during the following decade continued to highlight the potential of computerized statistical methods for solving the multivariate problems with which archaeologists deal. Among the most habitual multidimensional techniques implemented in archaeological research during those years can be highlighted the importance of correspondence, principal component, and cluster analysis. MVA case studies multiplied in a wide range of archaeological issues, from taxonomy to seriation or spatial analysis (Madsen 1988; Shennan 1988; Jones 1986). Those years are considered as the true founding era of quantification and multivariate statistics in archaeology, mainly due to the spreading of these methods worldwide.

Progress and diffusion of personal computers and specialized software during the 1990s shifted the focus of archaeological mainstream approaches onto computational methods, where geographic information system (GIS), databases,

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0397

and technological gadgets took over. A quick *n*-gram search on the internet shows a general tendency to reduction in the use of all major MVA techniques in scientific publications during this period. It was the era, too, of profound criticisms towards the general theoretical framework of processual archaeology, trying to provoke a paradigm shift to post-modern perspectives. Some of the most important texts that tried to synthesize the Herculean amount of work developed during the previous decades were written in that context (Baxter 1994), as well as the majority of attempts to integrate quantitative methods within archaeological theory and reasoning, a recurrent topic since the early 1980s (Gardin 1979).

Despite an increasing number of computational applications in archaeology, the twenty-first century has seen the recovery of applied quantitative practices in our discipline. That scenario includes some important enhancement in MVA techniques, as well as a continuous refinement of the theoretical frames of reference for archaeological reasoning (Barceló and Bogdanovic 2015). While new quantitative methods are being assimilated from formal sciences (Bayesian statistics, neural networks, system dynamics, graph-based models, non-Euclidean statistics, etc.), the procedures destined to address multidimensional datasets have encountered new stimuli in order to improve.

For example, by analyzing the application of MVA techniques in four of the main journals within the domain of archaeological sciences (*Journal of Archaeological Science*, *Archaeometry*, *Journal of Archaeological Method and Theory*, and *Archaeological and Anthropological Sciences*) during the years 2009–2016, a sustained interest in these kinds of procedures can be observed. Even taking into consideration the effects of monographic issues in the bias of topics, each one of these journals presents several papers on multidimensional methods in each volume. It should be noted, among others, the relevance of cluster analysis in the *Journal of Archaeological Science* (>30% of the total number of papers published each year) and the continued interest in principal component analysis in *Archaeometry* (≈13% of the total number of papers published each year).

Current research applications

There exist several forms of categorization for MVA methods, depending on either their purpose (data reduction, clustering, prediction, etc.), the nature of the variables used in the analyses (dependents or independents), or the kind of data (quantitative or qualitative). Generally, the most widespread classification establishes two main categories: dependence and interdependence techniques. The first assumes the existence of both dependent and independent variables, and they are aimed at determining whether the set of independent variables affects the dependent ones and how. On the other hand, interdependence techniques do not make any assumptions about the nature of the variables or specific hypotheses and they try to analyze how they interact between them.

MVA has had a major impact on four main archaeological kinds of problems: (1) the analyses of chemical composition of artifacts; (2) typological/morphological classification; (3) assemblage comparisons; and (4) spatial analysis (Baxter 1994). Taking into account the above-mentioned classification of multidimensional procedures and, in a broad sense, these four fields of application, it is possible to highlight some examples of their use in archaeology.

Dependence techniques

Dependence techniques try to validate empirically a previously developed hypothesis, and they are considered as explanatory or predictive approaches.

- Multiple regression analysis (MRA) (see REGRESSION AND CORRELATION ANALYSIS): It is assumed that the dependent variable is quantitative. It is typically used to predict the behavior of the dependent variable as a linear function of the independent variables. Some archaeological applications of MRA procedures include: (1) osteoarchaeological prediction of the age of the specimens from several measures on their bones; (2) partition of mixed archaeological collections by estimating the best combination of specified sets of sources in the composition; and (3)

prediction of an archaeological outcome, such as the amount of archaeological material in a specific spatial demarcation, from several independent variables.

- Canonical correlation analysis (CCA): It is assumed that the dependent variables are quantitative. Its main aim is to simultaneously relate several metric dependent and independent variables, by calculating linear combinations of each variable group that maximize the correlation between them. Some archaeological applications of CCA procedures include: (1) assessment of projectile point typologies; (2) isolation of distinct toolkits associated with different kinds of cooking features; and (3) comparison between factors regarding settlement trends and yields in close fields.
- Multivariate analysis of variance (MANOVA) (see ANALYSIS OF VARIANCE AND COVARIANCE): It is assumed that dependent variables are quantitative. This statistic uses qualitative independent variables to define different groups, for which it is assumed that mean score on the dependent variables will be statistically equal for every group. It is usually used in order to quantify the strength between variables by testing the differences between underlying unobserved latent variables derived from the variables in the dataset. Some archaeological applications of MANOVA procedures include: (1) assessment of the degree of variation in *raphide* size within and between plant species for understanding ancient plant exploitation; (2) analysis of similarity between assemblages to determine what groupings make sense based on morphological features; and (3) comparison of variables within time-sliced datasets in order to characterize different historical landscapes.
- Multiple logistic regression (MLR): It is assumed that the dependent variable is qualitative and binominal. The aim of this technique is to predict the probabilities of the dependent variable or, even, to suggest the effect of the independent variables on the nominal one. It is very similar to multiple discriminant analysis, but it can be used to answer the same research questions when the rarely attainable assumptions imposed

by its counterpart cannot be fulfilled. Some archaeological applications of MLR procedures include: (1) prediction of critical level of scalar stress on the basis of community size, assessing the probability that a group reaches a hotspot of size development critical for its internal cohesion; (2) comparison of different mitochondrial lineage scenarios in population models to analyze which of them best fits the observed data; and (3) weight of independent variables as beta values for an inferential probabilistic model for settlement location.

Interdependence techniques

The main aim of interdependence techniques is to describe or reduce reality by synthesizing the most relevant information of the dataset.

- Principal component analysis (PCA) (see PRINCIPAL COMPONENT ANALYSIS): It is assumed that the dataset values are metric. Its main goal is to obtain a two- or three-dimensional picture of complex multivariate data. If archaeological data are represented by a set of points in a multidimensional Euclidean space defined by several orthogonal axes, the purpose of PCA is to find a new set of them that best fit the actual spread of the data. This technique, therefore, involves finding a new and often smaller set of uncorrelated variables (*components*) linearly related to the old set that summarizes them in an effective way. Some archaeological applications of PCA procedures include: (1) identification of groups of chemically similar artifacts that could potentially be used to answer questions of provenance; (2) evaluation of the reliability of typologies in measuring the effects of variation in lithic reduction by describing distinctive assemblages; and (3) analysis of the influence of environmental and resource proximity measurements in occupation strategies and settlement location.
- Multidimensional scaling (MDS): It is assumed that the dataset values are metric. These methods iteratively seek a good-fit solution to the general task of embedding

Euclidean coordinates in a set of similarity relations between the objects. Usually, the similarities are represented in the form of an $n \times n$ symmetrical matrix of all pairwise distances. Unlike other ordination methods, MDS makes few assumptions about the nature of the data, becoming well suited for a wide variety of cases. Neither linear nor modal relationships are assumed for the data matrix and any distance measure between data points is allowed, unlike other methods. Moreover, because MDS operates on dissimilarities, no statistical distribution assumptions are necessary. Some archaeological applications of MDS procedures include: (1) determination of associations between variables and cases of experimental data, such as physical and chemical properties of ceramic artifacts; (2) evaluation of societal developments by producing gradients for a quantitative measurement of cultural change on a linear timescale; (3) comparison and representation of the relations between archaeological sites from their material assemblages; and (4) transformation of spatial processes to pseudo-Euclidean frames of reference based on their cost distance pairwise matrices, providing more exact insights of their spatial structures, taking into account the heterogeneous surface in which they take place.

- Cluster analysis (see CLUSTER ANALYSIS): The dataset values can be both metric and non-metric. This is a method for ranking entities in a small number of groups in such a way that similar subjects are placed in the same group. Cluster analysis is a useful starting point for other purposes, such as data summarization. Whether for understanding or utility, cluster analysis has long played an important role in a wide variety of archaeological analyses. Hierarchical agglomerative and partitioning procedures are among the most habitual approaches to this kind of analysis, but new scenarios, such as model-based clustering and fuzzy clustering, are growing in importance. The outcome from a clustering of a dataset may have little meaning, since the resulting clusters are not associated with any concept arising from the domain of study, but only from the inherent structure of the data. Some

archaeological applications of cluster analysis procedures include: (1) unsupervised ranking of archaeological artifacts by using their compositional data for creating homogeneous clusters; (2) creation of artifact typologies arising from different measurements of the entities composing the dataset; and (3) identification of patterns in point scatters at both the intrasite and intersite level.

- Correspondence analysis (CA) (see CORRESPONDENCE ANALYSIS): It is assumed that the dataset values are nonmetric. CA is a statistical exploratory tool whose popularity has steadily grown in the social sciences as well as in archaeology. It graphically represents the dependence between rows and columns of contingency tables. The visual display of data helps the interpretation and allows patterns to emerge. The technique reduces the number of dimensions needed to display the data points by decomposing the total inertia (i.e., the variability) of the table and defining the smallest number of dimensions capable to capture the data variability. Some archaeological applications of CA procedures include: (1) stratigraphy and formation processes, seriation, and chronology; (2) comparison of artifact assemblages; and (3) analysis of intrasite activity areas.

Future perspectives

As previously stated, MVA tries to reduce complex datasets into a form in which to obtain a better description of the data under analysis. This objective includes both analyzing relationships between measured variables and categorizing the ensemble of entities within the dataset into coherent classes. Nevertheless, archaeological data tend to be more complex than the inductive models that emerge from reduction analyses. Recent works have tried to deal with this problem by presenting several nonlinear forms of classification (Barceló and Bogdanovic 2015).

Those works emphasize the importance of a deductive framework, in which both conceptualize the classifications archaeologists are dealing with and reveal the inherent structure present within the data. While several forms of data

reduction are still solid tools for exploratory analysis, current trends in MVA are trying to develop more refined forms of supervised classification. Several limitations in available methods like clustering or discriminant analysis have been recently pointed out in that sense, highlighting other possible alternatives. An important step forward in the general framework of multidimensional applications can be shown with the introduction of *immersions* in pseudo-Euclidean spaces. These allow us to apply properly any multivariate method to analyze projected data that fits better the archaeological structure represented, in both compositional and spatial analysis problems.

Besides refinement of MVA techniques, other approaches to the same kind of multidimensional datasets are now breaking new ground, mainly in relation to fuzzy classifications and neural networks. The former approach assumes intermediate values for statements between true and false, and besides reflecting closer the archaeological reality, it also provides a method to quantify qualitative matters in terms of reliability or confidence. Entities in the dataset are assigned to different classes with indexes that reflect the probability of the assignment of each item to a typological class, as a form of uncertainty estimation (Nicolucci and Hermon 2015). Closely related to this topic is the neural network approach (see NEURAL NETWORKS), which can be used as a nonlinear fitting mechanism to find compositional regularities in a set of experimental data (Baxter 2006). This procedure learns by sequentially applying input vectors, while adjusting network weights according to a predetermined procedure. In this way, once trained, the network identifies any input pattern and tries to output the associate scheme previously learned, offering the possibility to understand complex and incomplete archaeological datasets. Relating MVA and new forms of semantic relationships beyond resemblance are encouraging the development of both this methodological field and archaeological reasoning.

Network Science

TOM BRUGHMANS

University of Oxford, UK

MATTHEW A. PEEPLES

Arizona State University, USA

Network science is the study of the collection, management, analysis, interpretation, and presentation of network data (Brandes et al. 2013). Network data consist of a set of nodes (individual or collective “actors” in a network) and associated edges (sometimes called relationships, connections, or links) defined between pairs of nodes. Nodes and edges can also be assigned attributes representing additional information such as the weight or type of ties, or the size or type of node. One of the most common goals of network science is the exploration of dependencies among edges, nodes, edge attributes, node attributes, or any combination thereof. A dependency simply refers to how nodes or edges relate to each other and how they affect each other’s behavior, existence, or outcomes across a network. Dependencies can be formally expressed as theories, with associated expectations for the importance and role of specific kinds of relationships in a given network.

In archaeological applications of network science, nodes are used to represent analytical categories defined by the archaeologist: for example, people, communities, objects, places, and events. Edges represent relationships between these categories as defined by the researcher: for example, friendship, proximity, similarity, and co-presence. Archaeologists often represent their theories about relationships among the objects of study as formal theories of dependencies, and use network science techniques to explore, visualize, and analyze networks in light of these theories: for example, the relationship between interaction and power dynamics among past communities, the structural factors or node/edge attributes influencing the spread of innovations through

past social systems, or the structure and evolution of transport or economic exchange systems.

Network science and related network approaches more generally have a particularly long history in the social sciences, and have become increasingly popular in many other disciplines since 2000 (Freeman 2004). Networks have proved useful for the study of phenomena as diverse as power grids, the Internet, transport systems, neurons in the brain, food webs, scientific collaboration, and the spread of infectious diseases. Although network science and related methods have seen sporadic application in archaeology since the 1960s, the approach has only gained considerable popularity in recent years (Brughmans 2013; Collar et al. 2015). This increase in popularity can at least in part be attributed to the more widespread availability of the computational resources needed to study large networks, the availability of user-friendly software, the popularity of network science in many other disciplines, and the rise of online social networks in the early 2000s, stimulating research in networks across all disciplines.

Archaeological applications of network science are extremely diverse, covering a wide variety of relational phenomena and ways of using network data for representation (for reviews, see Brughmans 2013; Collar et al. 2015; Knappett 2011). Despite this diversity in data and methods, one can distinguish two overarching groups of common approaches that draw on somewhat different network science techniques: (1) applications focusing on the representation of archaeological datasets as networks in order to characterize and analyze structural features of those networks, and empirically test theories regarding the relationships between network structure and attributes; (2) applications focusing on formally modeling theories representing the evolution of a past network, or a dynamic process taking place over a past network, through computational modeling, simulation, or related methods. In practice, many applications combine both approaches.

The first group of archaeological applications of network science typically relies on exploratory

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0402

techniques to aid visual exploration of datasets (such as different network layout algorithms), as well as the statistical exploration of datasets through analysis of structural properties of individual nodes or of networks as a whole (for example, centrality measures or network clustering metrics). Recent applications of such exploratory network approaches have relied on many different kinds of data for defining formal networks ranging from the physical locations of nodes, to similarities in or co-presence of material cultural categories, to line of sight visibility and geochemically sourced raw materials or objects (by no means a complete list). A particularly common approach in recent archaeological network studies has been the representation of archaeological sites or other units of analysis as nodes, while using the similarities between assemblages at pairs of sites as a means for defining edges. A wide diversity of similarity or distance indices can be used to create such archaeological similarity networks, although the most common in recent work have been co-presence of object types on pairs of sites and the Brainerd-Robinson similarity index. Common research topics addressed through such empirical networks include explorations of how network structure influences the attributes of individual nodes, or how node or edge attributes influence network structure and dynamics.

The use of exploratory network techniques is to some extent an equivalent alternative to other graphical and exploratory data analysis (see EXPLORATORY DATA ANALYSIS (EDA)) approaches more commonly used to explore archaeological data, such as tabular and geographical representations of data or summary statistics of datasets. However, network representation and exploration helps archaeologists to think explicitly about the role of relationships, which is often considered an advantage in archaeological research contexts studying relational phenomena. Moreover, many exploratory network techniques are developed to study patterns in an archaeological dataset that could not be derived without representation as a network data (such as paths through a network; the steps to take to get from node A to node B over the network; higher order relationships between sets of nodes), and therefore do not have equivalents among more frequently used tools in the archaeologist's toolbox. Network approaches are particularly well-suited to archaeological

research contexts where theories about the relationship between network structure and attributes can be explicitly formulated as expectations for patterns in formal networks. Such expectations can then be identified, analyzed, and visualized using exploratory network science techniques in order to evaluate specific theories. For example, Peeples and Haas (2013) defined networks of similarity based on the frequencies of different ceramic wares at archaeological sites across a large portion of the US Southwest, and then defined a measure of "brokerage" which was designed to characterize the degree to which each site served as an intermediate in relations spanning the network as a whole. They then used this empirical archaeological network to evaluate two competing theoretical models derived from the sociological literature on the expected relationship between brokerage and the growth and persistence of nodes, by comparing network structure to the attributes of individual nodes.

The second group of applications relies on computational modeling methods such as agent-based modeling or statistical network modeling for formally representing and testing theories of dependence. Common research topics include the spread of cultural innovations or the spread of information over past networks. For example, Graham (2006) studied the speed of the flow of information over different parts of the Roman road network, as it is known to us from historical sources. In another set of applications it is the network structure itself that is generated and evolved through a hypothesized dynamic process. Particularly common research topics include the interactions of past communities generating exchange network structures. For example, Knappett, Evans and Rivers (2008) modeled incoming and outgoing relationships of maritime interactions between Middle Bronze Age island communities in the Aegean. Where possible, the hypothesized theories of dependencies can also be validated or falsified with archaeological data. For example, Brughmans and Poblome (2016) modeled a process of trade in Roman tableware taking place over a hypothesized commercial network of Roman traders, and compared the simulated distributions of tableware with the archaeologically observed distributions to evaluate the plausibility of their theory.

Despite the increased popularity and the wide diversity of archaeological applications in recent years, network science still faces a number of daunting challenges for archaeological applications (for an overview, see Brughmans, Collar, and Coward 2016). One of the primary challenges relates to the uncertainty among archaeologists with regard to when and for what kinds of questions it is appropriate or useful to use network science techniques. Simply conceptualizing and describing a past phenomenon under study as a network (for example, a social network or a transport network) in itself is usually not a sufficient motivation to use network methods. Networks, in and of themselves, do not represent past phenomena, but rather are merely a formal way of exploring our archaeological data and theories about relationships. Another major challenge concerns the fact that many network science techniques have been imported from other social science fields and were not designed with the particulars of archaeological data in mind. Thus, a critical assessment of the specific assumptions and functions of particular techniques should become common practice before applying any “off the shelf” methods for archaeological study. A critical assessment of network techniques also implies an evaluation of the potential impacts of missing or imperfect data: sometimes archaeological data are too fragmentary to allow the use of specific network science techniques, or sometimes missing data will require a dramatically different way of interpreting the results of this technique than in the social science context where the method originated. Beyond this, the prominence of existing network science techniques commonly developed for research in the social sciences tends to stimulate the study of person–person relationships, sidelining the person–object and object–object relationships so fundamental in archaeology. This suggests that archaeologists may benefit from moving beyond the most common methods and beginning to explore a broader diversity of techniques, such as two-mode and affiliation networks, multiplex networks and interdependent networks, and longitudinal or temporal networks. Importantly, archaeologists also have the potential to help to expand the range of existing network science techniques through our focus on long-term change in social systems and spatial

data. Archaeology uniquely offers information about long-term changes in human behavior and society, whereas many temporal network science techniques are only developed for cases in the social sciences with a much finer chronological accuracy. Further, archaeology has a strong tradition of spatial analysis (see SPATIAL ANALYSIS), which many researchers have lamented has been woefully underexplored in network science more generally. Thus, although the challenges are considerable, we argue that the future for network science in archaeology is bright.

Neural Networks

ANA J. LÓPEZ and ALBERTO RAMIL

Universidade da Coruña, Spain

Artificial neural networks (ANNs) are computational algorithms (see COMPUTER APPLICATIONS IN ARCHAEOLOGY) inspired by the structure and functioning of the human brain. ANNs improve the performance of a particular task, without being reprogrammed. In general, ANNs have demonstrated to be very suitable for applications in which no model exists, but a basic set of input examples is given. In medicine, for example, ANNs are used to recognize diseases from a variety of health-related indices (for example, a combination of heart rate, levels of various substances in the blood, and respiration rate). In this case, no specific algorithm exists on how to identify the disease, but a set of representative examples of all the variations of the disease are known. More examples can be found, for example, in business-related domains, sociology, psychology, and manufacturing.

ANNs are applied in different areas because of their easiness to use and implement, their capacity to approximate any mathematical function, and their ability to obtain results from complex and inaccurate data. ANNs are adequate to solve problems related, for example, to the recognition of shapes or patterns, prediction, coding, control, and optimization.

Human brain, in which ANNs are inspired, is made up of cells called neurons highly interconnected by synapses where the transmission of information occurs. Likewise, ANNs consist of a set of processing units, *nodes* or *neurons*, massively joined by connections with an assigned adjustable parameter or *weight*. The activity carried out by an artificial neuron is simple: It receives information from nearby neurons, weighted by the connections weights (the sum of these weighted signals is the neuron input), and, by applying a certain mathematical function, the *transfer function*, calculates an output. As

opposed to conventional processors (present in most computers), which transform the information sequentially, according to a program stored in the memory, the processing units work in parallel in ANN systems.

The operation of an ANN consists of providing a set of output values for each input dataset. The output provided by the network depends on the structure of the network and the values of the weights. The set of numerical values representing that scheme of weights has not been programmed, but the network is able to *learn it* through a training process during which the connections among neurons are modified and adapted, according to a certain algorithm called a *learning or training algorithm*. After the training, the particular scheme of weights and transfer functions achieved are an internal code that allows the network to react correctly to future situations or data of the same kind as those used for training, but which it has never seen before: that is, the network gains *generalization* capacity. Therefore, the knowledge of a neural network, as opposed to a conventional processor, is not stored in a memory but distributed through the network itself.

A system with these features presents a number of advantages over a conventional processor. Each unit performs a simple computation and the reliability of the total computation performed by the system depends on the interaction in parallel with a large number of units—so that the system can continue its normal functioning, even if a small part of it has been damaged. Moreover, ANNs are able to work with distorted or incomplete information due to their capacity for generalization.

In summary, as Haykin (2009) points out, ANNs are inspired by the structure of the nervous system, with the intention of creating parallel, distributed, and adaptive information processing systems. These features allow them to solve problems characterized by a high degree of complexity, inaccuracy, and uncertainty.

There are two main aspects that characterize an ANN and determine its functioning: first, its

architecture, in other words, the way neurons are organized and the way information is transmitted among them; and, second, the training mechanism. Regarding the architecture, we can consider ANNs to be feedforward or recurrent networks. In feedforward networks, neurons are distributed in layers: an input layer which receives information from the exterior and an output layer which sends the results to the exterior; there can be one or more intermediate layers or *hidden layers* between them. These networks are the simplest with regard to implementation and they also make quick calculations. On the contrary, in the case of recurrent networks, neurons can be connected to neurons from previous layers, from their own layer, or to themselves, so the concept of layer disappears. These networks imitate more accurately the structure of the brain where feedback phenomena are essential.

Attending to the learning mechanism, a distinction tends to be made between supervised and unsupervised learning. The fundamental difference between these learning mechanisms is within the existence of an external agent (supervisor) that controls the learning process. The supervisor checks the network output in response to a particular input and, in the event that the output does not coincide with the expected one (ideal), the weights of the connections are modified in order to bring the output obtained closer to the expected one. The process of adjusting weights is performed iteratively and can be carried out in different ways. This type of learning is very useful in classification and function approximation problems. On the contrary, in an unsupervised learning mechanism, the network does not receive any information to indicate whether or not the generated output is correct. There are no comparisons to predetermined ideal responses. The network function is to find the regularities or categories that can be established among the data presented at the input. Data requirements for unsupervised learning are thus much easier and less costly to meet, but the capability of the network is significantly less than in the case of supervised learning.

In order to understand the increasing use of ANNs in the field of archaeology, it should be taken into account, as pointed out by Deravignone, Blankholm, and Pizziolo (2015), that one of the main characteristics of this discipline

is the fact of dealing not only with very complex phenomena, such as culture, society, and past economic aspects, but also with limited and imprecise datasets. In addition, the generalization capacity of ANNs allows for carrying out the data analysis without preconceptions or subjective influences, such as the a priori application of a theory or model. Moreover, it is worth mentioning the ease of ANN integration into automated systems, both for acquiring data and for carrying out the data discrimination or classification process. A review of the literature on the application of ANNs to archaeological data shows that most used models of supervised learning network relate to the multilayer perceptron (MLP), and those models of unsupervised learning network relate to self-organizing maps (SOM).

The MLP is one of the most used ANNs in any field; to the point that many people identify ANNs with this architecture. MLP is a feedforward network, using the *backpropagation error algorithm* as its learning algorithm. In MLP networks, a set of values whose output is known, the *training set*, is used, so that the weights are modified in order to minimize the error, that is, the difference between the desired response and the system output. The error information is entered back into the system by adjusting the system weights. A backpropagation network, containing at least one hidden layer with enough nonlinear units, can learn any type of function or continuous relationship between a group of input and output variables. This property turns the MLP into a flexible and nonlinear general-purpose tool. Attention must be paid to overtraining, which occurs when the network begins to “memorize” training data instead of “learning” to generalize from trend.

SOM are an example of unsupervised learning networks used in archaeology. This type of network is composed of two layers: the input layer and the output layer; the latter is organized as a two-dimensional map. The connections are feedforward and the learning is competitive; this means that only one of the output neurons (or a group of neighbors) is activated when an input pattern is presented to the network. The objective of this training is to categorize (cluster) the input data. SOM are normally used to provide visual aids because they allow to show the relationships among large

amounts of data that would require more dimensions (something impossible for humans) to be displayed properly.

Regarding applications of ANNs in archaeology, they can be included in the following types: the identification of geographic areas with high archaeological potential and the classification and/or discrimination of archaeological materials or sites. In this sense, Anemone, Emerson, and Conroy (2011) used an MLP to predict productive fossil localities by means of remotely sensing imagery data; the network was trained to recognize the spectral characteristics of known productive localities and other land cover classes in the area of study. The results of the classification were examined within a geographic information system (GIS) software package in order to determine which areas had a high potential of being fossiliferous, due to the similarity of their spectral signatures to those of known fossil localities. A similar method was applied by Deravignone et al. (2015) in order to predict the location of medieval Tuscan castles. The variables they used as the input of the network came from raster layers of the GIS, such as elevation, slope, distance to watersheds, and others related to social or economic aspects, such as the distance from other settlements or from the raw materials. The output is a predictive raster map for this kind of settlement. Regarding the classification of archaeological materials, the eventual objective of a number of studies was the automation of the process. In this sense, Ramil, López, and Yáñez (2008) and Aprile, Castellano, and Eramo (2014) applied MLP to archaeological potsherds. In the former case, the classification was based on laser-induced breakdown spectroscopy (LIBS) (see LASER-INDUCED BREAKDOWN SPECTROSCOPY (LIBS)) data and the network was trained to recognize the characteristic LIBS spectra of sherds from different provenances. In the work of Aprile et al. (2014), digital images were used for petrographical (see PETROGRAPHY AND CERAMICS) classification. In a different line of investigation, Nash and Prewitt (2016) used the MLP to identify patterns in projectile point typology. Moreover, Coppa et al. (2007) applied SOM to dental metrics (see DENTAL METRICS) data in order to determine that seven human teeth belonged to the same individual. In paleoanthropology, it is common to deal with missing

data, due to the difficulty of finding complete skulls, skeletons, or dentitions, which makes the analysis by other statistical methods, such as principal component analysis (PCA), difficult or even impossible. The application of ANNs avoids this problem and, furthermore, SOM is an unsupervised technique which is able to display overall similarities of the processed data and facilitates easy visualization and interpretation.

In summary, neural networks provide archaeologists with new tools from the field of artificial intelligence (see ARTIFICIAL INTELLIGENCE) to analyze the past. The algorithms mentioned in this entry and others that have been successfully used in various fields of science and technology can probably be applied to many other archaeological problems, such as pattern recognition in rock art, use-wear analysis of lithic tools, paleoecology studies, analysis of land utilization, or even migration and colonization scenarios for past human populations. Therefore, scientists and archaeologists should work together and their efforts will be rewarded with a deeper knowledge of our past.

Nonparametric Statistics

BENJAMIN M. AUERBACH

The University of Tennessee, USA

Nonparametric statistical methods provide an approach to analyzing data wherein the parameters of the underlying population from which a sample is taken are unknown. These methods therefore make mild assumptions about the data, rather than the more stringent assumptions required by parametric methods (see REGRESSION AND CORRELATION ANALYSIS; SAMPLING THEORY; ANALYSIS OF VARIANCE AND COVARIANCE; and DESCRIPTIVE STATISTICS). Primary among the assumptions in the parametric analytical approach is that data are normally (Gaussian) distributed in the population sampled. As nonparametric methods do not rely on this assumption, among others (such as linearity), they make useful alternatives to parametric methods when the statistical assumptions of the latter are violated.

The basic principles of nonparametric approaches and their application are reviewed herein. There are dozens of nonparametric methods available, some of which correspond to analogous parametric methods, such as two-sample mean comparisons (e.g., Student's *t*-tests), linear regression, correlation, and the analysis of variance. Given the breadth of nonparametric methods available, only a summary of these methods and their application is discussed herein. Emphasis is placed on the application of methods to address archaeological areas of inquiry.

All statistical methods are concerned with estimating measures of central tendency and the dispersion of data around those measures. Unlike parametric methods, which estimate the mean and the variance, nonparametric methods often use the median and the quantity of data on either side of the median. Thus, nonparametric methods are, overall, distinguished by ignoring magnitudes of data and instead focusing on the ranks of those data relative to each other. Because of this

approach, nonparametric statistical approaches are more resilient to the effects of outliers, skewed distributions, and kurtosis of data (Gibbons 1992). In addition, these methods allow the analysis of data that are not interval scale, such as ordinal and nominative data. Percentage data and ratios also should only be examined using nonparametric methods, the reasons for which are outlined in Allison et al. (1995).

An important limitation to all nonparametric methods is that they generally have less statistical power compared with parametric counterparts, given the same sample size and effect size (Zar 2009). Statistical power measures the ability of a statistical test to detect a significant result when one is actually present; tests with less power are more likely to fail to detect a result when it is present. Only when the requirements for parametric techniques are violated are nonparametric tests more statistically powerful (Buskirk, Willoughby, and Tomazic 2013).

Good statistical practice suggests that researchers determine the most appropriate methods for analysis *before* data collection commences (Zar 2009). Choosing between parametric and nonparametric methods, however, may not be possible until descriptive statistics and tests for normality are conducted on data. A key point to understand is that nonparametric statistics may always be used for assessing most questions, though in cases where statistical assumptions are met, parametric methods provide more robust results. In addition, many nonparametric techniques are versatile, and so the brief examples that are introduced here are not meant to be indicative or exhaustive. Researchers should consult the literature to see how these methods have been applied, or to ascertain whether there is a precedent for applying certain methods to the data in question.

Perhaps one of the most commonly encountered families of nonparametric methods are chi-squared analyses (see CHI-SQUARE ANALYSIS), which often are used as goodness-of-fit tests. Chi-square tests of association examine whether nominal frequency data are independently assorted among categories between two

nominal variables. That is, using this method, the presence of one trait, character, or state is not contingent on the presence of another; hence, this is the reason why the table used for these analyses is termed the contingency table (see Table 1 for an example). Archaeologists may use these analyses to evaluate whether the distribution of artifacts or other objects, for instance, is the same among features within a site, among temporal horizons, or between sites. In the example presented in Table 1, lithic points recovered from a site are categorized by two nominal variables: source material location and point type. The totals for rows and columns are used to calculate the expected frequencies for each value, which in turn are used to determine whether the lithic points in these two categories are independent; that is, are the lithic types associated with the raw source material?

Chi-squared analyses experience the benefit of simplicity in their calculation, but have limitations. Chief among this is if expected values are less than five, then chi-squared analyses may yield false results (i.e., type I (false positive) or type II (false negative) errors). One solution is to combine nominal variable categories, though this is generally not ideal, especially when levels of nominal variables are specifically chosen to address research questions. Alternatively, researchers may use nonparametric Fisher's exact tests or random resampling tests (such as those based on Monte Carlo) to address this limitation (Buskirk et al. 2013). In addition, chi-squared contingency tables cannot assess whether an observed frequency is different from one that is expected (for instance, if an isotopic frequency

is greater than expected); to perform this type of analysis, a binomial test should be used.

When examining the association of two variables measured on an ordinal or interval scale, we commonly think of correlation. Pearson's correlations, however, make parametric statistical assumptions, and so are inappropriate when data are not normally distributed or errors are correlated (as these will inflate correlations) (but see Chok 2010 for an alternative perspective on the resilience of Pearson's correlation in non-normal data). Two alternative correlation techniques are Spearman's rho and Kendall's tau. These correlation methods use a version of data ranking to determine the amount of independence between two variables. Kendall's tau has been shown to be more robust than Spearman's rho, in part because Spearman's rho is limited to bivariate correlation, while Kendall's tau may be computationally modified to calculate partial correlation coefficients (Siegel and Castellan 1988). Partial correlations examine the independent relationship of two variables while accounting for the shared correlation with one or more other variables. For example, one may want to assess the association between the weight of tempering materials used in ceramics and the size of vessels while accounting for the effect of paste weight.

Commonly, researchers want to know if measures of central tendency (i.e., means or medians) indicate that variables were taken from different source populations. In parametric statistics, these inquiries use a class of methods that fall within the general linear model, which includes Student's *t*-tests and the analysis of variance (ANOVA). There are multiple nonparametric analogs to these approaches. A variable in two

Table 1 Example of a contingency table used for chi-squared analysis of lithic points recovered from a single site and temporal horizon. The contingency table with frequencies of points and totals within each nominal category is shown on the left. Expected values, calculated using the chi-squared formula (Zar 2009), are presented on the right.

		<i>Lithic point type</i>			<i>Expected values</i>	
		<i>Fluted</i>	<i>Nonfluted</i>	<i>Total</i>	<i>Expected Shared</i>	<i>Expected Not shared</i>
<i>Source</i>	Local	23	12	35	21.94	13.06
	Exotic	19	13	32	20.06	11.94
	Total	42	25	67		

independent samples may be compared using the Wilcoxon–Mann–Whitney test, which is a blending of two ranking methods (the Wilcoxon rank-sum test and Mann–Whitney U test). This test is especially useful to determine whether one group of observations is shifted with respect to the other group, such as if the concentration of cultivar remains is the same between two sites, or between two time periods. Paired samples, such as those taken before and after an experimental treatment, are best compared with a modification of the Wilcoxon test, the signed-rank test. Alternatives are available for this test if data are paired and dichotomous: the sign test and McNemar’s test. These are less frequently encountered in archaeological settings, but they are useful when threshold effects or a single change in state is under observation. Finally, in the case where researchers wish to compare a variable among more than two groups, a nonparametric extension of the one-factor ANOVA is available through the Kruskal–Wallis test, which is an extension of the ranking methods used in the Wilcoxon–Mann–Whitney test and approximates a chi-square sampling distribution. Similarly, Friedman’s test, an analog of the repeated measures of ANOVA, allows comparisons of more than two related measurements, and so is an extension of the Wilcoxon signed-rank test. Kruskal–Wallis and Friedman’s tests are superior to multiple Wilcoxon–Mann–Whitney tests, as the former testing methods reduce the probability of a type I error that occurs when making multiple comparisons, much as an ANOVA reduces this error for Student’s t -tests (Zar 2009). The Kruskal–Wallis test results indicate whether the median of a variable differs between groups, but cannot show which group or groups differ. Likewise, Friedman’s tests only indicate if a change in a measure for a variable occurs between bouts for paired data. A post-hoc comparison test—which is like using multiple pairwise comparisons while mitigating the probability of type I error—can indicate which groups differ. The Nemenyi test is one such post-hoc method (see Zar 2009 for a more complete discussion of this test).

All the group comparison tests noted in the above paragraph may also be accomplished using resampling and permutation methods. With the emergence of fast computing power and software (see below), bootstrapping has

emerged as a common form of resampling. In a bootstrap with replacement, data are sampled a set number of times, and parameters (means, medians, variances) are calculated for each iteration. For example, in a dataset of 20 observations for a variable, a bootstrap with 100 iterations will sample 20 observations from the original data *with replacement*, and the mean of the sampled means for the 100 iterations may be compared against a comparative observed or expected mean. Similarly, the bootstrap may be used to calculate confidence intervals around an estimated parameter, which may be used in lieu of a p -value to show if groups significantly differ. This method circumvents the necessity of assuming a distribution for the data. Another approach is to determine parameters for each possible sample that may be taken from observed data *without* replacement. This methodology is the basis for permutation tests, which generally operate by comparing the test statistic (e.g., for a Wilcoxon–Mann–Whitney test) for the original observed data against all the random reorderings of those data, which, in the case of independent sample comparisons, are made between groups. A variety of applications of these permutation tests are available (Good 2005), and may be applied from one-sample tests to ANOVA and regression.

Often, researchers want to know the effect of one variable on another, and not their association or differences; this is measured through regression analysis. Regression analysis examines the relationship between two or more variables by plotting the values of one (or more) predictor variables against a predicted (or criterion) variable. In parametric methods, regressions have a series of assumptions that require large samples, normality, and homoscedasticity of data, as well as relationships between data that are linear, quadratic, or cubic. Often, such as with growth data, cyclical data, or variable data (e.g., atmospheric concentrations of carbon isotopes), such relationships cannot be assumed. For this reason, the relationship between variables described in a regression may best be represented by a weighted fit line, the LOESS (locally weighted scatterplot smoothing) regression (Fox 2000). This method uses a kernel function, wherein the density of data around each point in a data range is assessed, and points with greater data densities are given

greater weights. These weights are used to iteratively generate a smoothing polynomial line that presents the trend between the predictor(s) and the criterion.

A key conclusion to draw from the approaches listed above is that multiple methods are available to assess questions raised within archaeological fieldwork and laboratory work. Additional nonparametric methods, including those that use maximum likelihood and Bayesian approaches (see BAYESIAN STATISTICS), are available for comparing variables, groups, and parameters. Given the ongoing development of these methods, it is important to read broadly in the science literature and observe how other disciplines are applying nonparametric statistical tests. With ever-faster and greater availability of computers, these methods are becoming more common. Commercially available packages, such as SAS, SPSS, Stata, NCSS, and JMP, are all regularly updated to include more nonparametric methods and options. Perhaps the best software resource, however, is R (R Core Team 2013), which is freely available and has user-created software packages that include many statistical tests not yet available in other software, such as the Nemenyi test. Regardless of the software employed, careful consideration of the theory and applications of any statistical method must be undertaken to optimally and accurately arrive at answers to archaeological questions.

Poisson and Binomial Distribution

ALESSIO PALMISANO

University College London, UK

The binomial and Poisson distributions are two statistical methods suitable for calculating discrete archaeological phenomena, which means that they have been used for assessing the probability of the outcomes that occur. This section introduces these two distributions and comparatively shows their differences and similarities.

The binomial distribution is a means to model the likelihood of discrete multiple phenomena in which only two possible outcomes are possible, such as the presence or the absence of material evidence in a given archaeological context (Banning 2000, 124–125). The two possible outcomes of this distribution are generally designated as “success” (p) or “failure” (q). The binomial distribution describes the behavior of a random count variable X only if all the following conditions are met: (1) the number of trials (n) is fixed; (2) each trial has two possible outcomes as “success” (p) or “failure” (q); (3) the probability of success p is the same for each trial; (4) each trial is independent, meaning that the outcome of one trial does not affect that of any other. The binomial distribution is applied to cases such as coin flipping, where there is a fixed number of trials, the outcome is either a head or a tail, the probability of success (e.g., getting a head) is $p = 0.5$ for each trial, and the outcome of one flip does not affect the outcome of other flips. For the case in which a coin is flipped ten times and the number of heads is counted, the parameters of the binomial distribution will be the number of trials $n = 10$ and the probability of success $p = 0.5$, and the distribution is conventionally abbreviated as $B(10, 0.5)$. This means that there is a 50 percent probability of getting a head when flipping a coin ten times. Given that there are only two

possible outcomes, the probability of success (p) in flipping a coin for each trial is $P(p) = 0.5$, and the probability of failure (q) is $P(q) = (1 - p)$, which is $1 - 0.5 = 0.5$. Instead, the number of sixes by rolling a die ten times has a binomial distribution $B(10, 1/6)$. So, the probability of success p for each trial is 0.167, while the probability of failure q is $1 - 0.167 = 0.83$. In archaeology there are several different applications for the binomial distribution. For instance, paleobotanists use binomial distribution to measure the presence or absence of particular plant taxa in a fixed number of samples (Popper 1988, 63). This distribution has also been used to assess at the site of Casas Grande the likelihood of a co-occurrence of a particular decorative motif with male or female effigies (VanPool and VanPool 2006).

For instance, the binomial distribution can be applied to a scenario where the probability of finding an arrowhead in an excavation unit of 1 m^2 is 0.3, and the excavated units are 10. In this case the binomial distribution is symbolized as $B(10, 0.3)$. Therefore, it is possible to calculate the probability of finding one or more arrowheads in a given number of trials. Probabilities of a random variable X can be found by applying the following formula (VanPool and Leonard 2011, 80–81):

$$P(x) = \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x} \quad (1)$$

where $P(x)$ is the probability of success out of n trials, x is the specified number of successes (finding an arrowhead), n is the fixed number of trials, p is the probability of success on any given trial, and $(1 - p)$ is the probability of failure (q). The expression $\frac{n!}{x!(n-x)!}$ is known as binomial coefficient and the notation $n!$ stands for the factorial of a number, which can be calculated by multiplying a given number by all integers between itself and 1 (e.g., $3! = 3 \times 2 \times 1$).

Using Equation (1) it is possible to get the probability of finding four arrowheads (x) after

Figure 1 Probability (a) and cumulative distribution function (b) for binomial distribution B(10, 0.3), and Poisson distribution with $\lambda = 2$ (c, d).

excavating ten excavation units:

$$\begin{aligned}
 P(4) &= \frac{10 \times 9 \times 8 \times 7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1}{4 \times 3 \times 2 \times 1 (10 - 4)!} \\
 &\quad \times 0.3^4 (1 - 0.3)^{10-4} \\
 &= 210 \times 0.3^4 \times 0.7^6 = 0.20
 \end{aligned}$$

Figure 1 (a) and (b) shows the different probabilities and density function of finding zero to ten arrowheads and the cumulative distribution for the binomial distribution (10, 0.3).

The probability of finding from zero to four arrowheads is then the sum of these probabilities. The probabilities are 0.03, 0.12, 0.23, 0.26, and 0.20. Hence, the probability of finding four or fewer arrowheads is 0.84. The cumulative probability of finding more than four arrowheads after excavating ten excavation units is $1 - 0.84 = 0.16$.

Continuing excavating over and over again it is possible to calculate the long-term average of the expected successes (number of arrowheads found) over the entire population of trials (excavation units). The mean of a binomial random variable X is calculated by the following formula:

$$\mu_x = np \quad (2)$$

where n is the number of trials and p the probability of success. Hence, the mean of the binomial distribution after digging 20 excavation units is $np = 20 \times 0.3 = 6$.

The variance of the random variable X is $\sigma^2 = np(1 - p)$ and the standard deviation of X is just the square root of the variance, which is $\sigma = \sqrt{np(1 - p)}$. The variance in the binomial distribution B(20, 0.3) is $6(1 - 0.3) = 6 \times 0.7 = 4.2$, and the standard deviation is the square root, which is 2.05.

The Poisson distribution is useful for modeling and finding the probability for the number of events occurring in a specific interval of time or within a given area of space. A random variable X , the number of events in a fixed unit of time or space, has a Poisson distribution when the following assumptions are true: (1) the events occur independently of each other; (2) the average frequency that an event occurs in a fixed time or space does not change through time; (3) two events cannot happen simultaneously; (4) the probability of the occurrence of an event in a fixed interval is proportional to the length of the interval. Unlike the binomial distribution, the Poisson distribution does not model the

probability of the frequency of “successes” (p) or “failures” (q) occurring in a fixed number (n) of trials. Instead, it provides the expected number of events in a fixed unit of time or space. This distribution is usually used to test if specific events were generated by a random process. In addition, because the Poisson distribution is characterized by no fixed cutoff, the random variable X can be a positive integer from zero to infinity. The Poisson distribution closely approximates the binomial distribution when n is large, p is very small (one rule of thumb is that it should be no greater than 0.1), and $\lambda = \mu_X$. The Poisson probability of any given number of the variable X can be calculated with the following formula:

$$P(x) = \frac{\lambda^x e^{-\lambda}}{x!} \quad (3)$$

where x is the number of the events whose probability is calculated, λ is the average number of events occurring per unit of time or space, e is a constant that is approximately equal to 2.71828, and $x!$ is the factorial number of x .

The Poisson distribution can be useful to model events such as the number of patients arriving at an emergency room between 10 and 12 am, number of goals scored in a World Cup football match, the number of students enrolling at a university in a year, the number of phone calls received by the Police’s phone center between 11 and 12 pm, and so on. In archaeology the Poisson distribution has been generally used to test if past events have randomly occurred per unit of time and space. For instance, the rate of disintegration of radioactive ^{14}C per minute is described by a Poisson distribution (Banning 2000, 125; Buck, Cavanagh, and Litton 1996, 105). This distribution has also been used to assess if the spatial configuration of archaeological artifacts or sites in a given study area is the result of past random processes (Bevan et al. 2013; Crema, Bevan, and Lake 2010; Palmisano 2013).

Using Equation (3) it is possible to calculate the probability of the number of events (e.g., artifacts or sites) found within a given spatial unit (e.g., a square). For instance, in a scenario where 20 events are found in ten squares, and λ is 20/10 = 2, the probability of an empty square is given by the following formula:

$$P(0) = \frac{2^0 (2.718\ldots)^{-2}}{0!} = (2.718\ldots)^{-2} = 0.135$$

and the probability of a square containing one event is

$$P(1) = \frac{2^1 (2.718\ldots)^{-2}}{1!} = 2 \times 0.135 = 0.27$$

Probabilities for larger values of X are calculated in the same way to obtain the distribution shown in Figure 1c.

Although the graph does not show the probabilities for values higher than ten, this is just to save space. In fact, there is a low probability of having a square containing ten or more events. In the Poisson distribution it is theoretically possible to have hundreds of events within one square, even though that probability would be extremely low. Figure 1d shows the cumulative probability from zero to X for any specific value of X . This is useful to obtain the probability of finding more or fewer X events within a square. In the present example the probability of finding one or no events in a square is $0.135 + 0.27 = 0.405$. Once all probabilities are found, then it is possible to calculate the expected number of squares that can contain X events by multiplying the relevant probability by the total number of squares (Lloyd 2011, 248–249). In this case, the expected number of squares containing zero and one event is 1.35 and 2.7 respectively. Instead, the expected number of squares containing four events will be $0.09 \times 10 = 0.9$.

Comparing the expected frequencies with the observed data allows one to assess if the events are distributed randomly in a given study area. For instance, the expected number of squares containing ten events (0.0003) is close to zero according to the Poisson distribution. Nevertheless, if in the observed data there are one or more squares containing ten events, it means that the number of squares containing X events is more than expected and the events are clustered in one or more parts of the surveyed area. Poisson models are, therefore, useful to assess how well a null hypothesis of complete spatial randomness explains the observed distribution of artifacts or sites in a given study area.

Pottery Data Quantification

MARTIN KAMPEL

Technische Universität Wien, Austria

JURAJ SARKISJAN

Charles University, Czech Republic

What is pottery data?

Pottery sherd used to be one of the most overlooked artifacts found on excavation sites, because of its relative ordinariness and its frequent occurrence. Even though pottery sherd is still not considered to be esthetically appealing, the view on its importance changed slowly throughout the twentieth century, mostly because of the development of archaeology and the straightforward evolution of our ability to extract data. This development was accelerated even further by the application of interdisciplinary approaches, especially by computer technologies during recent decades. Pottery is now considered to have great potential for revealing additional information about its user and society, from analysis of the fabric, shape, and additional features of the pottery. Experienced specialists are able to extract information about the social and economic status of the user, his or her cultural affiliation, cultural development of the society, culinary habits, trade networks in the area, and so on. We can determine its *class* (e.g., plate, crater, cup), *form* (e.g., volute crater, column crater), *vessel size*, and *vessel thickness* from its shape. Additional features of the clay can be determined (e.g., *porosity*, *quality*), the *firing process*, and *inclusions* (granularity, grain size) from analysis of its fabric. Specialists can analyze additional features incurred by human interaction with the pottery: degree of abrasion from daily use, decoration, nondecorative deliberate markings like graffiti, potter's stamps or merchant marks, and repairs. Assessment and analysis of these straightforward attributes leads to the

extrapolation of further pottery data such as provenance, dating of the vessel, or the method by which the pottery was made (Barclay and Knight 2016).

Quantification

All the above-mentioned pottery data can be extracted from a single piece of well-preserved sherd. However, pottery is the most frequent artifact found at excavation sites and the majority of the excavated sherds are difficult to determine because they might lack features that would distinguish them from the rest of the assemblage. In order to extract data from the sherds collected from a surveyed area, specialists have developed various methods for its quantification. Orton and Hughes (2013, 21) stated that quantification is simply the answer to the question “How much pottery is there?”—whether in a context, feature, site, or other grouping. In broad terms, quantification is the measuring of the amount of each type of pottery in an assemblage, aiming to describe the assemblage in terms of the proportions of each type present and determine relative amounts of the different types of vessels present in a single context.

Common methods of quantification are as follows:

- Sherd count: counting every sherd, except those that are freshly broken. The amount is not an estimate.
- Sherd weight: recording the total weight of identified sherds.
- Estimated vessels represented (EVREP): the estimated number of vessels that are present in the assemblage.
- Estimated vessel equivalent (EVE): the most suitable measure for pottery, where a measurable fragment (usually a rim or bottom) is scored as a fraction of a complete vessel.

Using two or more of these measurements is preferable than just one; however, it is crucial to use a consistent approach for the site assemblage.

DOI: 10.1002/9781119188230.saseas0473

First attempts at using multiple measurements were made in the context of count and weight by Solheim (1960) and further developed by Orton (1985), and Schiffer (1987, 282).

Estimated vessels represented (EVREP) and mosaicking

The term estimated vessels represented (EVREP) was introduced by Orton and Hughes (2013, 172) and it represents the estimated number of vessels that are present in the assemblage. Specialists who use this method have to face an issue caused by the amount of sherds which are difficult to assign to a specific vessel. While the majority of sherds come from the body of the vessel and not from the easily distinguishable parts, like rims and bottoms, the estimate might become distorted. This issue was recognized in the past and various approaches were suggested:

- Minimum vessel count: Sherds are assumed to belong to the same vessel, unless we can prove that they belong to a different one.
- Maximum vessel count: Every sherd counts as one vessel, unless it either fits into another sherd or is demonstrably part of the same.
- Average of the minimum and maximum vessel count.

However, even these elaborate estimates are not generally considered to be reliable. In order to make this estimate more precise, a different approach using computer visualization (e.g., mosaicking) is needed to minimize incorrect assignment of multiple sherds to one vessel or differentiate the sherds more successfully.

Mosaicking is the process of the reassembly of an object from its pieces and it is very similar to the automatic assembly of jigsaw puzzles. Utilizing rotational symmetry of vessels manufactured on a potter's wheel enables the possibility to assign multiple sherds to one vessel even if there are gaps between them. Figure 1a shows a box filled with archaeological fragments, which could possibly fit to each other. Figure 1b illustrates manually identified, matching fragments.

Mosaicking can be seen as a special case of object recognition by approximate outline matching. The most common technique of mosaicking is 2D outline matching. Hori, Misakazu, and Ogasawara (1999) propose a method for joint detection among two potsherds designed for pottery fragment outlines. Their approach is based on a partial verification method of a pair of contours without knowledge of the shape features of a piece. Kong and Kimia (2001) approach the jigsaw problem in two stages: The first stage, local shape matching, aims to find likely candidate pairs for adjacent fragments; the second stage

Figure 1 Box filled with archaeological fragments and matching pieces.

represents ambiguities resulting from local shape matching. Matching is based on the notion of an alignment curve to represent correspondence between two curves.

Other techniques used are 3D outline matching and surface matching of fractured surfaces. The specific problem of identifying adjacent ceramic fragments by matching the shapes of their outlines was considered by Ücoluk and Toroslu (1999). They represent the 3D fragments by their boundary curves, from which curvature and torsion scalars are computed. A noise-tolerant matching algorithm serves to find the best match of two such circular strings. There is, however, no fully functioning technique that would succeed in actually reconstructing more than a few fragmented objects from the initial acquisition, thus proposing challenges for further research.

Estimated vessel equivalent (EVE)

The basis of EVE is the assumption that every sherd represents a portion of the whole pot of which it once formed a part. Specialists might assign these proportions to sherds as “scores” and add them up to find the total amount of vessel types. In practice, it is not usually possible to assign a score to every sherd, and one is limited to sherds such as rim sherds, whose size can be measured in terms of the proportion of the whole vessel. Since we are sampling the measurable sherds from an assemblage, we refer to the EVE (Orton and Hughes 2013, 174).

Concerning the rim or base equivalents, specialists use a diameter chart to estimate what proportion of the circumference of a vessel each rim or base represents, giving a completeness index (rim-equivalent or base-equivalent) that ranges from 0 to 100 percent. Additionally, a simple mathematical method, discovered by Orton and Tyers (1990), can turn this EVE into a number that has the same statistical properties as counts of objects. This number is called the *pottery information equivalent* (PIE), because 1 PIE contains as much information as one whole vessel. If we use these PIE values to calculate proportions of pottery types, they provide unbiased estimates of the relative abundance

of each type in the assemblage (Banning 2006, 106).

However, specialists who use quantification for a better understanding of the assemblage have to face the impossibility of determining whether the assemblage is complete, or whether it contains pottery sherds contextually belonging to a single period, or, if needed, one specific group of users.

From quantification to visualization

The growing need for maximizing the potential of the quantification and minimizing the errors caused by the incompleteness or redundancy of some sherds in the assemblage leads to the utilization of a new approach. Visualization is considered to be a tool for specialists who have to process the entire excavated assemblage, which allows a new way of understanding the large amount of data and also correct identification of redundant examples.

Visualization generally uses three inputs of data:

- 3D images represent 3D objects, which allow us to consider 3D volume as part of the entire 3D world. A 3D representation is a transition of an object in the real 3D world to an object-centered coordinate system, allowing object descriptions to be independent of the viewer. In order to quantitatively describe real-world structures, methods for extracting 3D information have to be investigated.
- A digital image defined as a 2D image represented by a discrete 2D array of intensities. This represents an object's appearance in grayscale or colors, has a certain resolution, and might be stored in JPG or GIF format.
- A sequence of images (video) represents how images change due to the motion of objects, point of view, or light source. In addition to the spatial features represented in a 2D image or single frame, videos enable a representation of object motion over time.

Traditional archaeological classification and reconstruction is based on the rim profile of the object, which is the cross-section of the fragment in the direction of the rotational axis of symmetry.

This 2D plot holds important information needed in order to perform archaeological research. Both correct profile and correct axis of rotation are therefore essential to reconstruct and classify archaeological ceramics.

Segmentation of the profile section

Specialists usually acquire the profile by using various traditional methods of documentation. The most common method is to use a combination of calipers or dividers and profile/contour gauges. The outer surface of the sherd is pressed into the profile gauge, which creates an imprint on the gauge. This imprint is redrawn on paper or a graphic tablet as the outer line. Then the thickness of the sherd is measured with calipers or dividers at regular intervals or at any particularly identifiable points (e.g., change of angle). The thickness, which determines the distance between the outer and inner profile, is tracked along the outer profile accordingly. The points are then connected, creating the inner profile and thus the whole profile of the pottery.

The profile should be first segmented into its parts, the so-called primitives, in an automatic way. The determined profile has to be converted into a parameterized curve and the curvature has to be computed (Bennett and MacDonald 1975). Local changes in curvature are the basis for rules required for segmenting the profile. Emphasis is placed on a hierarchical segmentation of the profile into rim, wall, and base by creating segmentation rules based on the expert knowledge of the archaeologists and curvature of the profile. Segments of the curve are divided by so-called segmentation points. If there is a corner point—that is, a point where the curvature changes significantly—the segmentation point is obvious. If there is no corner point, the segmentation point has to be determined mathematically.

By means of these curve points, several main segments of a vessel are distinguished: the rim, upper part, lower part, neck, shoulder, belly, and bottom. On the basis of the number and characteristics of these segments, different kinds of vessels can be classified. Segmentation is carried out only on the outer half of the profile (Orton

Figure 2 List of characteristic points.

and Hughes 2013), because the inner side does not contain information. The next step is to split the outer profile into its primitives by locating the characteristic points (see Figure 2):

- Inflexion point (IP): where the curvature changes its sign.
- Local maximum (MA): maximal point of vertical tangency.
- Local minimum (MI): minimal point of vertical tangency.
- Orifice point (OP): outermost point, where the profile line touches the orifice plane.
- Base point (BP): outermost point, where the profile line touches the base plane.
- Point of the axis of rotation (RP): where the profile line touches the axis of rotation.

These points are found within the transformed data. A formalized approach uses mathematical curves (e.g., cubic splines) to describe the shapes of vessels and their parts. The profile is thus converted into one or more mathematical curves (interpolation or approximation by B-splines). Figure 2 shows an example of an automatically segmented pot with the characteristic points detected.

3D object reconstruction

In order to describe the relationship between 2D image structures and their corresponding real-world structures, methods for extracting 3D information need to be investigated. According

to Marr (1982), we see 3D vision as a 3D object reconstruction task to describe 3D shape in a coordinate system independent of the viewer. The shape of a 3D object is represented by a 3D model. Two main classes of 3D models are identified: Volumetric models represent the “inside” of a 3D object explicitly, while surface models use only object surfaces. Unlike 3D models, depth maps or range images describe relative distances from the viewer of surfaces detected in the scene. For 3D object reconstruction the following three major steps are identified: (1) data acquisition, (2) range image processing, and (3) model reconstruction.

Data acquisition is the first and one of the most important tasks in a chain of 3D reconstruction tasks, because the data quality of the sensed images influences the quality of the final results. El-Hakim, Beraldin, and Picard ((2002) specify the quality of data by a number of requirements: high geometric accuracy, capturing all details, photo-realism, full automation, low cost, portability, flexibility in applications, and efficiency in model size.

Blais (2004) reviews the last 20 years of range sensor development. Each view acquired by the range sensor represents a portion of the object. Multiple views of the same object have to be combined to produce a complete model of the object. The process of combining range data into one single coordinate system is called range image registration. Approximate transformation between the views can be carried out either automatically by a calibrated robot or shifting unit or by the computation of the rigid transformations that add and track the data from one view into the other view. The most commonly used algorithm for registering is the iterative closest point (ICP) algorithm. ICP improves the registration of two overlapping surfaces by calculating the unique transformation that minimizes the mean square distances of the correspondences between the two surfaces.

The final-step model reconstruction refers to a surface fusion process, which consists of multiple tasks such as large dataset reduction, outliers removal, surface triangulation, and hole filling. The goals are to minimize global registration error, caused by the propagation of noise from

one surface patch to the other, and to preserve the topology of the original object.

The increase in large quantities of 3D data causes many complex issues for existing algorithms within the area of data representation; hence the need for revision of existing methods. Because of the rising tendency for obtaining large quantities of 3D data, the majority of existing algorithms face issues of computational complexity and data representation and need to be revisited. Important topics in 3D vision deal with scene capture and self-calibration, 3D modeling under time-varying motion, deformation, or illumination, 3D modeling from large and complex datasets, and 3D view registration and recognition.

Predictive Modeling

PHILIP VERHAGEN

Vrije Universiteit Amsterdam, Netherlands

Archaeological predictive modeling can be defined as a technique trying to predict “the location of archaeological sites or materials in a region, based either on a sample of that region or on fundamental notions concerning human behavior” (Kohler and Parker 1986). The basic premise of predictive modeling is that human spatial behavior is to a large extent predictable, which implies that the locations where people lived and performed their daily activities can be identified on the basis of statistical and/or explanatory models.

Predictive modeling is used in archaeology for two purposes. First, it is a planning aid for cultural resource management (CRM) in order to assess the risks of disturbing archaeological remains during development projects. Second, predictive modeling is applied as a tool to develop and test scientific models of human locational behavior. In academic contexts, therefore, predictive models can be considered as heuristic tools (Verhagen and Whitley 2012) that can play an important role in formalizing and quantifying theoretical notions on the development of settlement patterns and land use.

Predictive models can be made following two different strategies, usually named “inductive” and “deductive” (Kamermans and Wansleben 1999), but more accurately described as “data driven” and “theory driven” (Wheatley and Gillings 2002). In “data-driven” modeling, the location of archaeological sites in a study region is compared with a number of parameters that are considered to be important to settlement location (such as slope gradient, soil type, or distance to water), using geographic information systems (GIS). The results of this quantitative site location analysis can then be extrapolated to areas where no archaeological data are available, and will thus result in a prediction of site

densities for the whole area studied. A popular technique for data-driven predictive modeling is logistic regression, but many more options are available, including ecological niche modeling, Monte Carlo simulations, and Bayesian statistics. However, despite the current state of sophistication of statistical modeling, it is still very difficult to state which statistical technique performs best, since there are hardly any case studies available where methods are compared.

The second, “theory-driven,” approach bypasses most of the statistical complexity by defining theoretical assumptions about the parameters influencing human spatial behavior. For example, it can be assumed that early farming communities preferentially located their settlements in environments well suited for agriculture and animal husbandry, which in turn can be related to parameters such as the abundance of certain soil types within a particular radius. Expert-based weights are given to the parameters included, and the resulting models are then compared to the known archaeological record in order to judge their performance. This approach has the advantage that it can include more sophisticated theoretical frameworks that are based on causal explanation, it can include human agency as a factor, and it is not directly dependent on archaeological datasets (Verhagen and Whitley 2012). Deciding on a best possible model, however, still implies comparing various parameter weights with the actual archaeological data.

The roots of predictive modeling can be traced back to the days of “new archaeology,” and in particular the development of site catchment analysis in the 1970s. Archaeologists became aware that human settlement is intimately linked to its environmental setting, which also implied that it should be possible to predict the locations suitable for human settlement. Around the same time, CRM developed in the United States in response to legislation aimed at the protection of cultural heritage. In the absence of sufficient data to identify all archaeological sites in a region, predictive modeling answered the need for a more comprehensive mapping of cultural resources. When GIS arrived on the

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0475

scene in the early 1980s, it allowed for much more advanced computer-based mapping and modeling and paved the way for further proliferation of predictive modeling, initially in the United States (Judge and Sebastian 1988) and later also in Europe (van Leusen and Kamermans 2005). From the outset, predictive maps served two specific purposes. First, they were intended to influence the decision-making processes of planners and to convince them that developments should take place in the least-sensitive areas; and second, they were to guide the archaeological investigations once developments started, by making reasoned choices on where to concentrate research efforts within the constraints of available time and money. Since then, predictive modeling has been applied in numerous cases around the world. Its cost-effectiveness in CRM has been proven, and it has provided a basic degree of protection to zones of high archaeological potential in those regions where it is included in CRM policies.

Nevertheless, predictive modeling has encountered substantial criticism from archaeologists. This is because it will never be able to accurately predict all archaeological remains. The models are only as good as the data and theories that have been used to create them, since we can only extrapolate from the existing state of archaeological knowledge. In that respect, there is no real difference between theory-driven or data-driven approaches. For many archaeologists the risk of “wrong predictions” and their undesired consequences for the protection and investigation of the archaeological record in CRM is unacceptable. From a scientific point of view, however, discrepancies between prediction and data can be the starting point to develop new theories about site location and/or to direct future data collection practices, which could also be a guiding principle for decision making in CRM.

The potential flaws of predictive models were summarized by van Leusen and Kamermans (2005):

- The archaeological input data are usually not representative of the full archaeological record, and the archaeological record itself is a biased reflection of human activity in the past; therefore, we cannot expect that models based on existing archaeological datasets will

accurately predict all locations of past human settlement.

- The predictor variables used are often based on modern-day environmental datasets, which may not be at the right level of detail and accuracy for predictive modeling purposes, and may not accurately reflect the situation in the past.
- Sociocultural variables are usually not included.
- The temporal resolution of predictive models is limited, since this is determined by the archaeological and environmental input datasets used.
- Testing of predictive models is often done in a haphazard way, and in most cases does not involve a representative field survey; the distinction made between areas of low and high probability has instead often led to a policy of not surveying the low-probability zones, and in this way, a self-fulfilling prophecy will be created (Wheatley 2004).

Predictive modeling has often been criticized for restricting itself to a limited set of “environmental” variables. This can partly be attributed to the fact that there are relatively few relevant datasets available that cover large areas. The inputs most often used are derivatives of digital elevation models (in particular slope and aspect), and, to a lesser extent, topographical, geological, and pedological maps. This approach has been successfully applied in many cases, but the datasets are sometimes used in a very uncritical way. Sociocultural variables (such as distance to roads, or to specific archaeological sites), on the other hand, are much more difficult to implement in predictive models because of the scarcity of relevant data and lack of quantifiable theoretical models, although there is no inherent barrier to including them (see for example Whitley et al. 2010).

Ideally, the desired degree of accuracy of a predictive model should determine what is needed in terms of data and knowledge. In practice, however, predictive models are often made on the basis of data that happen to be available, and for this reason they can vary considerably in their accuracy. It is therefore extremely important that the models are tested, both internally in order to establish the uncertainties in the parameters and

archaeological data used by means of sensitivity analysis, and externally by adding independent, representative archaeological data. Establishing the representativeness of archaeological datasets, however, is often very difficult, since in many cases there is insufficient information about the intensity and methods of survey applied and about the influence of potential biases, such as the visibility of archaeological remains on the surface. These factors highly influence not just the number of archaeological sites found, but also the types of sites that can be discovered successfully (Verhagen 2008).

Creating and testing archaeological predictive models is therefore a complex exercise, at the end of which the results need to be translated into terms that can be easily implemented in CRM and other planning contexts. Formal statistical assessments do not necessarily play an important role in this. Instead, a number of explicit and implicit assumptions about the importance of specific archaeological remains, their state of preservation, and the costs of excavating them are used as well to assess the archaeological and financial risks of development plans. Thus, creating predictive models is only one stage in the decision-making process surrounding archaeology in spatial planning, and as such their role in CRM should not be overemphasized. However, since they are used at the beginning of the planning process and will direct decision making in subsequent stages, their accuracy should be a major concern to archaeologists, developers, and planners alike.

Principal Component Analysis

AMBER M. VANDERWARKER

University of California, Santa Barbara, USA

JON B. MARCOUX

Salve Regina University, USA

Principal component analysis (PCA) is one of a number of exploratory statistical techniques that can be employed to recognize, interpret, and present patterns in multivariate datasets. PCA is ideal for investigating relationships between variables and cases, as well as characterizing significant data trends that involve multiple variables (Baxter 1994; Madsen 1988; Shennan 1997). Generally, PCA is ideal for exploring continuous measurement-based data associated with artifact morphology, elemental composition, and, as shown in this entry, spatiotemporal contexts. Below we outline how PCA works as a method of analysis and summarize two published cases that use this method to elucidate archaeological patterning.

For the sake of introduction, imagine a dataset consisting of values for 14 different measurements taken from a sample of stone projectile points (blade length, blade width, stem length, stem width, thickness, etc.). A perfectly accurate representation of the relationships among the variables and cases in this dataset would require 14 dimensions; however, humans can only simultaneously visualize up to three variables at a time. PCA and related techniques, including correspondence analysis and multidimensional scaling, allow analysts to overcome this dimensional limitation through ordination—a method that reduces the number of dimensions required to represent the many relationships among cases and variables in a dataset.

PCA achieves this dimensional reduction by grouping together variables in the dataset that are correlated. In most archaeological applications, covariance is expressed as a matrix of

standardized correlation coefficients (r) for all variables, with values ranging between -1.0 and 1.0 (Baxter 1994, 65–66). PCA aggregates highly correlated variables together into summary variables called principal components (PCs). While each principal component is comprised of correlated variables, PCA requires that the principal components themselves be uncorrelated. When represented visually, these uncorrelated principal components can be seen as perpendicular (or orthogonal) axes that define a new space within which the variables and cases can be plotted with minimal loss of the original information (Shennan 1997, 281–282). PCA then determines new positions for variables and cases within this transformed space.

The technique provides powerful tools for exploring the relationships between variables and cases through a combination of numeric and visual results. There are three important and related types of numeric information calculated for each principal component—eigenvalues, component loadings, and component scores. An eigenvalue (or latent root) is most easily conceived of as the total amount of variation in a dataset accounted for by a particular principal component (Shennan 1997, 279). Eigenvalues themselves are difficult to interpret directly. Therefore, they must be transformed by dividing each value by the number of variables in the dataset and then multiplying by 100. The resulting value is the percentage of total variation in a dataset explained by that component. It is always the case that the first principal component will have the highest value, and subsequent components will be defined by decreasing eigenvalues (Baxter 1994, 67).

PCA results typically include a table listing component loadings for variables (rows) and principal components (columns). Component loadings are standardized measures of covariation between each principal component and each variable in a dataset and can be interpreted exactly like correlation coefficients (r) (Shennan 1997, 278). The analyst can determine which variables are most closely related to a particular

principal component by identifying the variables with strong positive or negative loadings. By squaring component loadings, the analyst can also determine what percentage of variation in each variable is explained by a principal component. These two procedures are essential for identifying and interpreting the data trends that are being marked by the principal components.

PCA also provides a table of numeric results called component scores relating cases (rows) to principal components (columns). Component scores can be thought of as translated coordinate values marking the position of a case along each of the principal components. Each component score is derived from the original variables by multiplying the standardized value of each case by the component loading of each variable and summing the results for all of the variables (see Shennan 1997, 285–187 for a detailed discussion). Analysts can best understand the data trends captured by principal components by examining cases with component scores at both the positive and negative ends of a principal component.

While the numeric results of PCA are crucial for identifying and interpreting patterns in multivariate datasets, the visual results of PCA are perhaps better suited for presenting those patterns to an audience. Visual representation of data is often the main goal of ordination methods like PCA; these are scatterplots that depict the relationships between variables and cases along axes representing the principal components. Typically, PCA results are presented as separate scatterplots for variables and cases, respectively. Because component loadings are used as coordinates for variables and component scores for cases, the scatterplots distill much of the data contained in the numeric results; spatial clustering of variables or cases suggests similarities. Additionally, because both cases and variables are plotted within the same relative principal component dimensions, the relationships between variables and cases can be represented spatially (Baxter 1994, 57–59). Looking at the paired scatterplots, *variables* occupying the same relative principal component space as a cluster of *cases* can be said to have significant influence over the observed similarities among cases in the cluster (Shennan 1997, 295–296). Scatterplots also allow the analyst the additional option of coding cases with different symbols to represent other dimensions,

such as time or space, which may aid in further understanding the data trends.

To demonstrate the utility of PCA with respect to archaeological data, we present two cases from the published literature. The first case highlights the efficacy of using PCA to quantitatively integrate seemingly disparate types of data: animal bone fragments and carbonized plant remains. Most often these two types of data are analyzed separately, which can create an artificial conceptual divide between the meat and vegetable portions of the diet (VanDerwarker and Peres 2010).

In their case study from Formative-period Veracruz, Peres, VanDerwarker, and Pool (2010) consider how sociopolitical status and contexts of discard vary with respect to plant and animal foodways at the multi-mound political center of Tres Zapotes. Based on architectural and artifactual analyses, Peres and coauthors were able to define three broad types of socioeconomic space: nonelite domestic space, elite households, and ceremonial areas. In analyzing how sociopolitical space varies in relation to food use, the authors begin by conducting independent analyses of the archaeobotanical and zooarchaeological datasets. Independent analysis of the plant data did not reveal much difference in plant presence or abundance between these three contexts; however, beans appear to have been restricted to elite contexts, and nonelite contexts appear to have had elevated levels of tree fruit remains. Independent analysis of the faunal data revealed a greater concentration of deer and dog remains in elite contexts versus fish and turtle remains in nonelite contexts. Patterning in ceremonial areas was less clear when compared to the elite and nonelite household areas.

In order to clarify the patterning in ceremonial areas, and in line with the idea that ancient food practices should be conceptualized as cuisine in which ingredients are combined to form distinct dishes, Peres et al. (2010) turned to PCA. To make the plant and animal datasets comparable, each dataset was standardized in a similar manner. Frequencies of plant fragments were summed by type (maize, fruits) for each context (nonelite, elite, ceremonial), and each sum was then divided by the total plant weight in that context. Likewise, animal bone frequencies were also summed by type (deer, dog, fish, turtle), and

divided by total bone weight for each context. The resulting continuous data were then used in the PCA. The integration of these datasets revealed patterning that was not apparent through the independent analyses alone. Both plant types (maize, fruits) mapped directly onto nonelite domestic contexts, with values that did not overlap with the elite or ceremonial contexts. Given that maize was present in similar frequencies across all three contexts in the independent analysis, the fact that the PCA results associate maize specifically with nonelite contexts suggests that plant food frequencies in elite and ceremonial contexts were overwhelmed by a much higher frequency of meat resources. Thus, the PCA reveals that the nonelite diet was focused almost entirely around plant foods, with meats being preferentially incorporated into elite diets and ceremonial events. Such an interpretation would have been impossible without integrating these datasets using PCA. While this case employs subsistence data, any type of material data could be incorporated, with the caveat that all data used in the PCA are transformed into continuous data and standardized in similar ways to make them comparable.

PCA is also useful when trying to determine spatial clustering of multiple variables. In order to be appropriate for this type of analysis, the cases must represent discrete spatial contexts (e.g., features, units, houses). The case study we use to exemplify PCA as a tool of spatial analysis is a burned house structure from the Ravensford site (ca. 1700–1830 CE), located in western North Carolina (VanDerwarker, Alvarado, and Webb 2014). The structure was excavated in a series of contiguous 1×1-m units, totaling 69 units. Given the details of timing, burning, and house abandonment, the plants recovered from the floor of this structure relate to activities that occurred within it toward the end of its use-life. PCA was thus used to determine how the structure's ancient inhabitants organized food storage and processing tasks.

VanDerwarker and colleagues (2014) use the 1×1-m excavation unit as the spatial unit, in which each unit represents a single case in the analysis. The variables are represented by the plants that were identified in those units, and all plant frequencies were standardized to total plant weight for each respective excavation unit.

The first PCA run identified several units that formed two distinct clusters. The first cluster was represented by a single unit located near the southern corner of the structure. The second cluster included five contiguous units in the northwestern area of the structure. In order to determine additional patterning, a second PCA was conducted after excluding the units from clusters identified in the first analysis. The second run resulted in one additional unit being included in cluster 1, one additional unit being included in cluster 2, and a third unit creating a new cluster (cluster 3).

Based on the spatial clusters defined through the PCA, the authors were able to interpret how interior food storage and processing were organized within the house. Cluster 1 was composed mostly of nutshell and maize remains, suggesting that the southern corner of the structure was an area dedicated to staple food processing. Cluster 2, located in the northern corner of the structure, was dominated by fruit seeds and interpreted as an area of dried fruit storage. The authors suggest that fruits were dried and then placed in storage by hanging them from ceiling rafters. When the house burned and the roof collapsed, these fruits likely fell to the floor amid a background of general food-processing debris. Cluster 3, in the west-central area of the structure, was dominated by bottle gourd rind and seed fragments. Bottle gourds were primarily used as liquid storage containers and were probably suspended from the rafters, much like the dried fruits. When the roof beams collapsed during the structure's incineration, the gourds would have crashed to the floor and shattered, littering the floor with a high density of bottle gourd rind fragments. This example demonstrates how PCA can be employed to define clear activity clusters in situations where material remains represent abandonment debris or primary refuse.

Complex multivariate statistics like PCA can seem daunting to the quantitatively challenged archaeologist, but PCA's utility in dealing with large datasets to reveal novel patterning is clear. The cases above exemplify the interpretative power of PCA to move us beyond what we can learn from simple univariate analyses. PCA is thus an important technique to curate in our toolkit of archaeological data analysis.

Quantum Analysis

KARL M. PETRUSO

The University of Texas at Arlington, USA

The study of the origins and evolution of systems of measurement (a discipline referred to as historical metrology) has attracted both scholars and amateurs who share an interest in discovering mathematical patterns—the bygone analogues of our pounds and kilograms, yards and meters, and quarts and liters. Determination of the absolute values of the standards underlying early systems of measurement is a fundamental task of historical metrology. Empirical studies are based on two classes of evidence: *metrical artifacts* that provide primary or direct evidence, for example, balance weights, rulers, and standardized containers for liquid and dry measures manufactured according to specific desired volumes; and *products fashioned according to standard units of measure* of mass, length, and volume, for example, ingots, architectural spans, and certain clay vessels, whose relevant metrical dimensions reflect rational and practical series that are useful in evaluation, accounting, and design. These items might constitute secondary or indirect lines of evidence. Clearly, the credibility of any argument for metrical configuration of either class of data will be a function of sample size. Inasmuch as both of these lines of evidence derive from surviving material remains, they invite archaeological inquiry. To the extent that systems of measurement are tools of industry and of trade, moreover, they can provide a window into understanding economic and political relationships.

Scholars have traditionally focused on weight metrology, since identifiable balance weights often survive to their original or approximate target masses (depending on their material and preservation). Their masses can be determined quickly, and the corpus of published balance weights with reliable and precise archaeological contexts is constantly growing, permitting us to address interesting questions about economics,

trade, design and aesthetics, and cultural and political relationships in antiquity. The mathematical structures of these systems are windows into understanding the origin and evolution of quantitative thought, since they are proxies for pure number, witnesses to how early peoples quantified their raw materials and finished goods. Since much recent scholarly effort has focused on modeling ancient measurements in the data-rich eastern Mediterranean, that region will provide the primary example for this entry.

History of research

Early attempts to isolate standards of weight in early societies empirically—that is, by weighing identifiable well-preserved balance weights that are arguably close to their originally intended masses, as well as items presumed to have been manufactured to targeted masses—were based on recognition of ratios of mass relating balance weights found on individual archaeological sites, and later comparing those results over broad regions. The general assumption was that the ratios expressed simple series of denominations. Multiples of a one-unit standard might run in one or more of the following series:

2, 4, 8, 16, 32, ... (binary)

5, 10, 20, 25, 50, 100, ... (decimal)

3, 6, 12, 15, 20, 30, 60, 120, ... (sexagesimal)

Smaller denominations have typically included simple unit fractional quantities, including $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, ... , doubtless because doubling and halving are the quickest and most precise activities to execute on a double-pan balance. Other unit fractions (notably $\frac{1}{3}$) are attested, and when precision in accounting demanded it, non-unit simple and useful fractions were generated, including $\frac{2}{3}$ and $\frac{3}{4}$, as well as fractions with denominators 5, 10, and 12, inter alia. As a rule, we may expect numeration and metrology in ancient systems to have been relatively uncomplicated, and to reflect the same ease of use that characterizes everyday

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

DOI: 10.1002/9781119188230.saseas0484

counting and measuring in our day. The empirical evidence indeed bears this out. Thus, recovering the mathematical structure of an ancient system ought to be a relatively straightforward, common-sense exercise in arithmetic, and indeed much progress has been made on decoding ancient systems using nothing more than intuitive trial-and-error, goodness-of-fit approaches.

Case studies

In a few cases, inscriptional evidence exists in the form of numerical symbols and/or words incised in balance weights and other artifacts in the primary/direct category that designate their values within a system. The present author demonstrated the value of such markings in the case of balance weights from Greece, Crete, and the Cycladic islands in the later Aegean Bronze Age, ca. 1900–1200 BCE (Petruso 1992). Among more than 200 specimens identified as balance weights, about a quarter of them show simple markings. Most of the inscribed specimens (primarily discs of stone or lead), including many that are unmarked, leave no doubt that the most commonly attested Bronze Age Aegean weight system was based on a unit standard in the vicinity of 60–65 g. Simple dots, circles, and strokes borne by these artifacts suggest multiples in a primarily duodecimal structure (1, 2, 3, 4, 6, 8, 12, 24) and unit fractions $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, and $\frac{1}{8}$, although $\frac{2}{3}$ and $\frac{3}{2}$ are also indicated. Notably, each of two 24-unit weights excavated from two Minoan Cretan palaces bears two large and four small circles (to be read “two tens, four ones”, as their masses confirm), indicating a decimal base for numeration. Both Linear A and Linear B Aegean scripts were primarily tools of inventorying and accounting. Not surprisingly, weighing also demonstrably functioned on a base-10 system.

The best-known example of an exercise in historical metrology is the long-term project of Oxford engineering professor Alexander Thom (d. 1985), who made thousands of precise linear measurements over many years at Stonehenge and many other stone circles in the British Isles with a view to determining whether they were designed and constructed according to standard spans. For the purpose of introducing the

analyses that follow, a unit standard (or as it became known, a *quantum*) might be represented mathematically by the simple equation:

$$X = Mq + \epsilon \quad (1)$$

where X is the value of an observation on a metrical scale (e.g., feet, grams, cubic centimeters), M is an integer, q is the quantum on which the system is based, and ϵ is an error term that can be positive or negative.

The data suggested to Thom a repeating span of 0.83 meters (2.72 feet), which he labeled the “Megalithic Yard,” and its double, 1.66 meters (5.44 feet) (Thom 1955). He refined and defended his argument subsequently for three decades. Although scholars have long been intrigued by the possibility that architectural units of measure existed over a wide region and many centuries, Thom’s arguments inspired scant consensus, and today have few adherents.

In the same year that Thom published his megalithic yard analysis, S. R. Broadbent (1955) introduced an explicitly quantitative approach to isolating candidates for standard units in a disparate population of data. He defined a “quantum hypothesis” test:

$$y_i = \beta + 2r_i\delta + \epsilon_i \quad (\text{for } i = 1 \text{ to } N) \quad (2)$$

where β and 2δ are constants (2δ is the quantum), r_i is zero or a positive integer, and ϵ_i is the error of observation. His goal was to develop a means to analyze groups of observations that were either known or suspected to have been quantally configured. In this, he sought an objective method for identifying particular quanta rather than simply testing chosen candidates for goodness-of-fit.

The most abiding contribution to date with respect to methodology in ancient metrology, however, was proposed by Oxford mathematician D. G. Kendall (1974). He chose a subset of the rich database of megalithic measurements amassed by Thom, namely the diameters of 169 ancient stone circles in Scotland, England, and Wales. Kendall developed the following equation:

$$\phi(q) = \sqrt{\frac{2}{N}} \sum_{j=1}^N \cos(2\pi\chi_j q) \quad (3)$$

where $\phi(q)$ is a “score” of the likelihood that a tested quantum X was the standard on which

the system was constructed; N is the number of specimens; and $\sqrt{\frac{2}{N}}$ is a scaling factor based on the population size.

The introduction of Kendall's "cosine quantogram" (Kendall 1974, Figures 4 and 5) was a significant step in the evolution of historical metrology. It obviates the inclination of the researcher to argue for a particular standard on the basis simply of goodness-of-fit. Rather, iteration of the function tests very many possible candidates over a continuum from relatively small to about half the value of the largest observation in the dataset of N observations. The computer-generated graphic output is easily comprehensible and permits rapid identification and ranking of potential quanta.

The procedure has great utility. Each $\phi(q)$ is either positive or negative in sign for a given quantum candidate. Negative scores are rejected, and only relatively high positive scores merit further consideration. The higher the score, the greater the likelihood that the associated value might have been the quantum—or one of the quanta—on which the system was based, rather than simply randomly distributed. Kendall's analysis of the megalithic circles confirmed that a value of 5.44 feet was indeed prominent in Scotland, but as a measure for British megalithic architecture overall, it was not found to be statistically compelling.

John F. Cherry (1983) was the first to apply the cosine quantogram procedure to advantage with respect to another purported ancient linear measure, namely a "Minoan foot" on which the design and construction of the Cretan Bronze Age palaces had been proposed.

Recent research

The cosine function defined by Kendall has gained broad acceptance by archaeologists. Cemalettin Pulak (1996) put it to good use in his metrological analysis of an extraordinary corpus of balance weights from two Late Bronze Age merchant shipwrecks (ca. 1300 and 1200 BCE) excavated off the south coast of Turkey in the 1960s and 1980s. More recently, scholarly interest in the quantal search procedure has evolved to the point where the method itself is now receiving

scrutiny. Edward Castle (2000, 128–40) and Jari Pakkanen (2011, 143–66), who have focused on populations of both ancient balance weights and linear spans, are concerned *inter alia* with, respectively, the relationship between sample size and the reliability of the highest-scoring tested quanta returned in analyses, and the ability of Kendall's function to isolate two or more standards in a population of observations. The directions of this research promise to refine the precision of future quantum analyses as well as the plausibility of interpretations, especially for those societies that employed multiple unit standards.

R Coding and Modeling

BEN MARWICK

University of Washington, USA

Introduction

R is a programming language and computing environment useful for statistical and geospatial analysis, data visualization, and mapping. It is significant as the most widely used scientific programming language in archaeology. This entry will briefly describe the origins of R and survey its distinctive features, including how it enables reproducible research. It will also highlight some current uses of R in archaeology, and suggest some possible future directions.

R was originally developed in New Zealand in the early 1990s as an academic research project to create a language for introductory data analysis courses. It is closely related to the S language and S-PLUS software. Currently it is maintained by an international community of about 20 computer scientists and statisticians, and has six-monthly update cycles to the core libraries. It is widely used in academia, especially statistics and social sciences, and in industry. R has a vibrant online community that is friendly to novices, as well as numerous informal user groups, an annual conference (useR!), a non-profit organization (R Foundation), and a peer-reviewed journal (*The R Journal*).

Distinctive features of R

R differs from other software commonly used for data analysis in two important ways. First, R is an open-source software program. This means that, unlike commercial data analysis software (e.g., SAS, Stata, SPSS, JMP, SigmaStat, etc.), R is free for anyone to download and install (cf. PAST, JASP, and PSPP). The full details of all its algorithms are publicly available for inspection and modification (cf. JASP and PSPP), unlike

for many other programs where these details are not available to the user (cf. PAST, and all commercial software). Second, for many archaeologists a spreadsheet program such as Microsoft Excel is their primary tool of data analysis and visualization. The primary mode of interaction is by manipulating cells in the spreadsheet, and through mouse-clicks to access commands in the drop-down menus. R differs from all other statistical software because it is not a spreadsheet program and has very few mouse-driven actions. Instead, R has a prompt to which typed commands are interactively sent to the R interpreter.

As a programming language, R gives the user great flexibility through access to a vast variety of methods. The user is not limited to built-in functions, but can easily create new ones. The R interpreter evaluates commands typed by the user, and the computed output is printed to the screen or stored for later use. These typed commands are saved in a plain-text R script file, which becomes a record of all the steps in a data analysis.

Unlike most other software, R also has an environment. Any type of data file (e.g., Excel, CSV, OBJ, TIFF, JPEG, shapefiles, netcdf, etc.) can be imported into the R environment and manipulated, analyzed and combined with other data using a coherent and integrated set of operations.

After a data file is imported into R, it is usually represented as a vector (a one-dimensional set of values of the same type, i.e., numeric, character, logical, etc.) or combinations of vectors. A frequently-used data structure in R is the data frame. This is analogous to a table of data in a spreadsheet, and formally in R is a list of different types of vectors of equal length. Many functions (named sections of code that perform a specific task) in R are optimized for working with data frames, and can perform summary statistics and complex operations very quickly on these structures. Related structures include the matrix (vectors of the same length but only one type, equivalent to a table of only numbers or only characters, cf. the standard structure for MATLAB software), and the list (a vector that

The Encyclopedia of Archaeological Sciences. Edited by Sandra L. López Varela.

© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.

DOI: 10.1002/9781119188230.saseas0631

combines elements of any data type). Lists are complex, hierarchical objects (a list can contain lists) that are frequently used during looping operations to automate complex actions efficiently for many items (e.g., hundreds of Excel files need to be read and computed on).

R is primarily a functional programming language, which means that the basic unit of activity when using R is typically the evaluation of mathematical or computational functions. The basic installation of R contains over a thousand functions. In addition to these built-in functions, an R user can install over 10,000 packages of more specialized functions freely contributed by R users. These packages are distributed via three major online code repositories: Comprehensive R Archive Network (CRAN), Bioconductor, and GitHub. Some examples of add-on packages specifically for archaeologists include *archdata* (contains 11 archaeological datasets from around the world reported in published studies), *FedData* (automates downloading of geospatial data from several US and international federated data sources), *zooaRch* (analytical tools to make inferences on zooarchaeological data), and *recexcavAAR* (functions for 3D reconstruction and analysis of archaeological excavations, including methods to reconstruct natural and artificial surfaces based on field measurements).

In recent years a collection of R packages known as the tidyverse has emerged as a major new direction for the R language (Wickham and Grolemund 2016). These packages share common philosophies of tidy data, which is an approach to representing and manipulating data where variables are in columns, observations are in rows, and values are in cells. Tidyverse packages are designed to work together, with common data representations and simple, consistent programming interfaces for fast, efficient data analysis and visualization. For an archaeologist learning R for the first time, the tidyverse approach and packages are an ideal starting point.

Reproducible research using R

In many areas of social science there is an emerging concern to improve the reproducibility of published results. Reproducibility is the

cornerstone of science, and often defined as the ability to recompute the results of a data analysis, given a dataset and information about the data analysis pipeline (Marwick 2017). One contributor to this crisis is the use of mouse-driven software such as SPSS, where many steps of the analysis pipeline are not preserved in a convenient form, or at all. This makes it difficult to reproduce results obtained by pointing-and-clicking. Using R is one aspect of solving the problem of irreproducible results. When data are analyzed using a programming language such as R, the saved R script file contains a full record of every decision made during data analysis, and can be shared with other researchers.

In addition to scripting every step of the data analysis, R also integrates with several other technologies to enable reproducible research. R code can be written among narrative text using the R Markdown text formatting system. Markdown is a simple, easy-to-learn, open-source language for formatting documents. This means that entire journal articles and theses can be written in R Markdown, with code and text interwoven together in the same document (Figure 1). Using the Pandoc program (included with RStudio), the R Markdown document can be executed, or rendered into a standard format such as PDF or Microsoft Word, so that the R code is run and the figures and tables for the manuscript are generated and inserted in place in the output documents.

The significance of this use of R in manuscript preparation workflow is that it avoids the typical practice of copying and pasting output from a statistical software program (e.g., SPSS) into a word-processing program (e.g., Word). Copying and pasting separates a result from the steps that generated it, making it impossible to trace the decisions made during an analysis. Copying and pasting is also error-prone because mistakes or ad hoc, undocumented modifications to output can be introduced to the text during revision cycles. R Markdown provides a simple convenient workflow for writing code and text to easily reproduce the results of a data analysis.

Another advantage of using R and R Markdown is that the data analysis pipeline behind an article or thesis can easily be shared with other archaeologists by sharing the R Markdown documents that generated the output document. This

Figure 1 A screenshot from the RStudio program showing how R can be used for reproducible research. In the left panel is a text editor, where we write plain text and code in an R Markdown file (known as a Rmd file). In the right panel is the output that is produced when the Rmd file is “knit,” or rendered, into a document. In this example, the Rmd has been knitted to produce a HTML file, but we could also produce a PDF or Microsoft Word document from the same Rmd file. The first paragraph of the text in the example demonstrates how to use markdown for basic text formatting (e.g., a heading, a URL, bold and italic text). The second paragraph shows how R code can be embedded inline in the text. The rendering process automatically runs the code and inserts the result in the text; here, it computes the number of rows in the “cars” dataset and inserts the result (50) in the rendered document. The text in the gray region on the left is a chunk of R code that produces the plot in the HTML file on the right. We use `echo=FALSE` in the code chunk to specify that the code chunk is not displayed in the HTML file; we see only the plot that the code generates. This method of writing text and code in the same document enhances reproducibility because the methods of data analysis (i.e., the R code) are explicitly included in the same document as the text, and the code can be easily and repeatedly run to generate results. This removes the need to copy and paste tables and plots from other software into the text, eliminating transcription errors and confusion about where a particular result came from.

is important for scientific archaeology because it enables more efficient adoption of new methods, and more rigorous checking of new results to establish their correctness. Furthermore, an archaeologist using R who does not make their code openly accessible upon publication is missing an important opportunity to increase the visibility and impact of their research.

A related tool that is often used with R to improve the transparency of data analysis is Git, the free and open-source version control system. Using Git with R means that researchers can track changes they make to their code and text files. Each decision point can be recorded, even if it is later deleted from the final document. Git allows collaborators to compare versions of code and text, retrace errors, explore new approaches in a structured manner, while maintaining a full audit trail. Several free web services have

user-friendly tools for collaborating in the open or privately with code and documents written with R and Markdown that are tracked using Git (e.g., GitHub, GitLab, BitBucket). The `rrtools` package at <https://github.com/benmarwick/rrtools> (Marwick, Boettiger, and Mullen 2017) includes instructions, templates, and functions for making a basic compendium suitable for doing reproducible research with R, Git and other related tools.

Current uses of R in archaeology

R’s flexibility as an analytical tool means that it is currently used by archaeologists for a wide variety of applications. An online “task view” page at <https://github.com/benmarwick/ctvarchaeology> contains an annotated list of R

packages relevant to archaeological research. Specialist studies of typical archaeological items such as stone artifacts, animal bones, isotopes, and sediments have all been done to publication quality entirely with R. R has also emerged as the tool of choice for several computationally intensive subspecializations in archaeology.

Archaeological modeling in R

Archaeological modeling in R means representing archaeological data for a purpose. This means that the data stand for something in the real world, such as past human behaviors or site formation processes. The purpose is often to gain new insights into the relationships between observed variables and their possible behavioral and environmental correlates. Statistical modeling in R takes archaeological data and combines it with model formulae, equations, uncertainty and randomness to test hypotheses about how the system being modeled actually works. For any kind of modeling, from linear regression to exotic machine learning method, R is ideal for identifying patterns in data, classification, untangling multiple influences, and assessing the strength of the evidence. In R, a statistical model is often expressed with formula notation, for example $y \sim x$. This can be read as “ y is modeled as a function of x ,” where y is a response variable whose content we are trying to model with x , called the explanatory variable. Following this notation, a typical linear regression model in R will look similar to this `fit <- lm(y ~ x)`, which is the R code for the traditional mathematical representation of $y_i = \beta_0 + \beta_1 x_i + \epsilon_i$.
